The main purpose of the *Journal of Educational Psychology* is to publish original, primary psychological research pertaining to education across all ages and educational levels. A secondary purpose of the *Journal* is the occasional publication of exceptionally important theoretical and review articles that are pertinent to educational psychology.

**Change of Address:** Send change of address notice and a recent mailing label to the attention of Subscriptions Department, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee periodicals forwarding postage.

**Single Issues, Back Issues, and Back Volumes:** For information regarding single issues, back issues, or back volumes, write to Order Department, American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242.

**Microform Editions:** For information regarding microform editions, write to University Microfilms, Ann Arbor, MI 48106.

**Manuscripts:** Submit manuscripts electronically through the Manuscript Submissions Portal found at [www.apa.org/journals/edu](http://www.apa.org/journals/edu), according to the Instructions to Authors found elsewhere in this issue (see table of contents). Correspondence regarding manuscripts should be sent to the Editor, Karen R. Harris, Vanderbilt University, *Journal of Educational Psychology*, Box 507 Peabody College, Nashville, Tennessee 37203-5721. The opinions and statements published are the responsibility of the authors, and such opinions and statements do not necessarily represent the policies of APA or the views of the Editor.

**Copyright and Permission:** Those who wish to reuse APA-copyrighted material in a non-APA publication must secure from APA and the author of the material written permission to reproduce a journal article in full or journal text of more than 500 words. APA normally grants permission contingent on permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of \$25 per page. Permission from APA and fees are waived for those who wish to reproduce a single table or figure from a journal for use in a print product, provided the author's permission is obtained and full credit is given to APA as copyright holder and to the author through a complete citation. (Requesters requiring written permission for commercial use of a single table or figure will be assessed a \$25 service fee.) Permission and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use more than a single table or figure of their own material commercially (but for use in edited books, fees are waived for the author only if serving as the book editor). Permission and fees are waived for the photocopying of isolated journal articles for nonprofit classroom or library reserve use by instructors and educational institutions. A permission fee may be charged to the requester if students are charged for the material, multiple articles are copied, or large-scale copying is involved (e.g., for course packs). Access services may use unedited abstracts without the permission of APA or the author. Libraries are permitted to photocopy beyond the limits of the U.S. copyright law: (1) post-1977 articles, provided the per-copy fee in the code for this journal (0022-0663/08/\$12.00) is paid through the Copyright Clearance Center, 222 Rosewood Drive, Danvers, MA 01923; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center. Address requests for reprint permission to Permissions Office, American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242.

**Electronic Access:** APA members who subscribe to this journal have automatic access to a 3-year file of the journal in the PsycARTICLES® full-text database. See <http://member-s.apa.org/access>.

**Reprints:** Authors may order reprints of their articles from the printer when they receive proofs.

**APA Journal Staff:** Susan J. A. Harris, *Senior Director, Journals Program*; Skip Maier, *Director, Journal Services*; Paige W. Jackson, *Director, Editorial Services*; Clark Munsell, *Account Manager*; Jodi Ashcraft, *Advertising Sales Manager*.

The **Journal of Educational Psychology** (ISSN 0022-0663) is published quarterly (February, May, August, November) in one volume per year by the American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242. Subscriptions are available on a calendar year basis only (January through December). # Teacher–Student Support, Effortful Engagement, and Achievement: A 3-Year Longitudinal Study

Jan N. Hughes, Wen Luo, Oi-Man Kwok, and Linda K. Loyd  
Texas A&M University

Measures of teacher–student relationship quality (TSRQ), effortful engagement, and achievement in reading and math were collected once each year for 3 consecutive years, beginning when participants were in 1st grade, for a sample of 671 (53.1% male) academically at-risk children attending 1 of 3 school districts in Texas. In separate latent variable structural equation models, the authors tested the hypothesized model, in which Year 2 effortful engagement mediated the association between Year 1 TSRQ and Year 3 reading and math skills. Conduct engagement was entered as a covariate in these analyses to disentangle the effects of effortful engagement and conduct engagement. Reciprocal effects of effortful engagement on TSRQ and of achievement on effortful engagement were also modeled. Results generally supported the hypothesized model. Year 1 variables had a direct effect on Year 3 variables, above year-to-year stability. Findings suggest that achievement, effortful engagement, and TSRQ form part of a dynamic system of influences in the early grades, such that intervening at any point in this nexus may alter children's school trajectories.

**Keywords:** student–teacher relationship, academic engagement, reading, math, elementary grades

Children's academic achievement in the early grades forecasts academic and mental health outcomes throughout their school years and into early adulthood (Alexander, Entwisle, & Horsey, 1997; Campbell, Helms, Sparling, & Ramey, 1998; Entwisle & Alexander, 1988; Finn, 1989; Roeser, Eccles, & Freedman-Doan, 1999; Stevenson & Newman, 1986). Given the importance of a good academic start to school, many researchers have investigated factors that affect children's school readiness skills and early academic trajectories (for reviews, see Future of Children, 2005; Perry & Weinstein, 1998; Shonkoff & Phillips, 2000). Whereas researchers previously focused on child and family contributors to early achievement, recent investigations have assessed the impact of aspects of the classroom and school context that promote or impede children's achievement (Burchinal, Peisner-Feinberg, Pianta, & Howes, 2002; Crosnoe, Johnson, & Elder, 2004; National Institute of Child Health and Human Development Early Child Care Research Network, 2003; Rimm-Kaufman & Pianta, 2000; Roeser et al., 1999). Teacher–student relationship quality (TSRQ) has emerged as an important aspect of the elementary classroom context that has implications for children's concurrent and future academic and social adjustment in school (Birch & Ladd, 1997, 1998; Howes, Hamilton, & Matheson, 1994; Pianta, Steinberg, & Rollins, 1995).

Researchers employing longitudinal designs have found that students who experience teacher–student interactions characterized by high levels of warmth and support or low levels of conflict gain more in achievement (Connell & Wellborn, 1991; Hamre &

Pianta, 2001; Hamre, Pianta, & Downer, 2006; Ladd, Birch, & Buhs, 1999; Pianta & Stuhlman, 2004; Skinner, Zimmer-Gembeck, & Connell, 1998). However, to capitalize on the potential of this classroom resource for improving young children's achievement trajectories, it is important to identify the more proximal mechanisms by which the teacher–student relationship affects achievement. Several investigators have suggested that students who experience an accepting and warm relationship with their teachers will be more capable and motivated to comply with classroom rules and teacher expectations (Brophy, 1983; Furrer & Skinner, 2003; Gest, Welsh, & Domitrovich, 2005; Wentzel, 1998). This increased engagement in classroom learning activities, in turn, is expected to lead to greater achievement gains.

Despite the intuitive appeal of this reasoning, the empirical support for such an indirect model of the effects of TSRQ in the early grades is limited in several ways. First, few studies have employed longitudinal designs that maintain temporal precedence consistent with the hypothesized causal pathways (i.e., TSRQ → engagement → achievement) and statistical controls for prior levels of both engagement and achievement (Skinner et al., 1998). These methodological limitations reduce confidence in conclusions about mediating processes because alternative causal linkages cannot be ruled out (Cole & Maxwell, 2003). Second, the few studies that have been conducted with children in the early school grades have employed measures of classroom engagement that combine different types of engagement (Ladd et al., 1999), thereby making it impossible to disentangle the unique contribution of each type (Fredricks, Blumenfeld, & Paris, 2004). Third, studies have failed to test for the reciprocal effect of engagement on TSRQ. Consistent with transactional (Sameroff, 1975) and developmental systems (Lerner, 1989, 1998) theories, developmental change results from the dynamic interaction between individuals and contexts. Thus, unidirectional models are likely to be inadequate representations of developmental processes.

The purpose of this study was to test an indirect model of the effect of TSRQ on first-grade children's academic achievement over a 3-year period, beginning when children were in first grade. The conceptual model, presented in Figure 1, predicted that TSRQ at Year 1 would affect achievement at Year 3 and that this effect would be mediated by the effect of TSRQ at Year 2. The model included reciprocal causal paths from effortful engagement to TSRQ and from achievement to effortful engagement. To test the unique contribution of effortful engagement to achievement, above the effects of antisocial or conduct engagement, the model also controlled for the effects of prior levels of conduct engagement on Year 3 achievement. Before we review the theoretical and empirical bases for the hypothesized model, we address the multifarious definitions of classroom engagement and the importance of distinguishing between different types of engagement.

### Definitions and Types of Classroom Engagement

Although an extensive literature dating from the 1960s has investigated school and classroom engagement, the construct of engagement has experienced something of a revival in recent years, stimulated by the growing recognition that student disaffection with school increases with additional years in school and is a major factor in student achievement and dropping out of school (Fredricks et al., 2004). In their thorough review of school engagement, Fredricks et al. (2004, p. 60) identified

three broad types of school and classroom engagement: *behavioral engagement* (involvement in academic and social or extracurricular activities), *emotional engagement* (positive and negative reactions to people and activities at school), and *cognitive engagement* (similar to the ideas of investment in learning and intrinsic motivation). Whereas emotional and cognitive engagement have been emphasized in research with middle school and high school students (Connell & Wellborn, 1991; Finn, 1989; Midgley, Feldlaufer, & Eccles, 1989; Ryan, Stiller, & Lynch, 1994; Skinner & Belmont, 1993), behavioral engagement has tended to be the focus of research with elementary students (Alexander, Entwisle, & Dauber, 1993; Birch & Ladd, 1997; Buhs & Ladd, 2001; Miles & Stipek, 2006) and is the focus of the current study. Fredricks et al. (2004) further divided behavioral engagement into three subtypes: conduct, involvement in learning tasks, and participation in extracurricular activities. Studies with elementary students have focused on the first two subtypes of behavior engagement. Conduct engagement is variously defined in terms of antisocial and prosocial behaviors and compliance with classroom rules (Alexander et al., 1993; Gest et al., 2005; Ladd et al., 1999; Miles & Stipek, 2006; Normandeau & Guay, 1998; Trzesniewski, Moffitt, Caspi, Taylor, & Maughan, 2006; Wentzel, 1998). Involvement in learning has been variously defined by "time on task" (Gettinger, 1985; Greenwood, 1991; Rimm-Kaufman, La Paro, Downer, & Pianta, 2005) and by effort, attention, self-direction, and persistence in the classroom (Connell & Well-

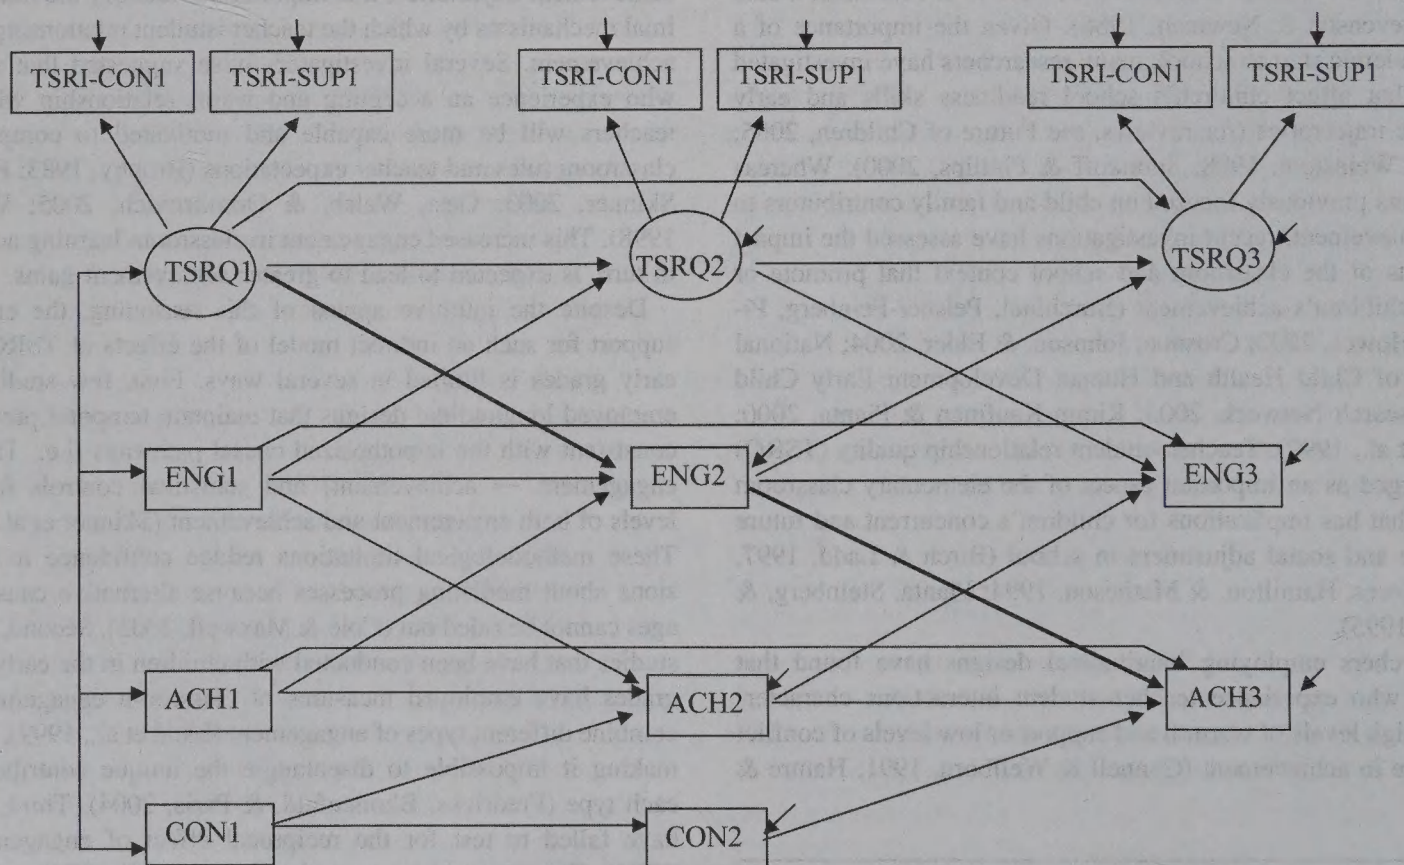

Figure 1. Hypothetical model. The bold lines represent target indirect effects. TSRI-CON = Teacher Student Relationship Inventory Conflict subscale; TSRI-SUP = Teacher Student Relationship Inventory Support subscale; TSRQ = teacher-student relationship quality; ENG = effortful engagement; ACH = either math or reading achievement; CON = conduct engagement.

born, 1991; Furrer & Skinner, 2003; Ladd et al., 1999; Normandeau & Guay, 1998; Skinner & Belmont, 1993).

Because researchers studying the effects of school and classroom engagement on achievement have differed in their definitions and measures of engagement, it is difficult to integrate findings across studies. Often, researchers incorporated a wide variety of constructs in their measurement of engagement, an inclusiveness that makes it difficult to determine the unique precursors and consequences of different types of engagement. In the current study, we assess both conduct engagement and effortful engagement, a construct similar to involvement in learning. *Effortful engagement* refers to the volitional, or effortful, aspect of involvement in instructional activities and includes trying hard, not giving up in the face of difficulty, and directing one's attention to instructional activities. Similar to effortful control (Rothbart & Ahadi, 1994; Rothbart & Bates, 1998; Rothbart & Jones, 1998), effortful engagement is viewed as having a basis in an individual's temperamental impulsivity and attentional capacities yet emerging as a result of the transactions between the child and his or her environment across time. Thus, we expect that effortful engagement will evince moderate stability across time and contexts. Our particular interest is in the effect of the quality of the teacher-student relationship on changes in children's levels of effortful engagement in the classroom and, consequently, on children's academic achievement.

### Effect of Effortful Engagement on Achievement

Longitudinal investigations have documented that high levels of antisocial engagement (or low levels of prosocial behavior) predict declining academic performance (Feldhusen, Thurston, & Benning, 1970; Huesmann, Eron, & Yarmel, 1987; Miles & Stipek, 2006; National Institute of Child Health and Human Development Early Child Care Research Network, 2004; Trzesniewski et al., 2006; Wentzel, 1991). Conversely, high levels of effortful engagement predict improving academic performance (Alexander et al., 1993; Greenwood, 1991; Skinner et al., 1998). However, few researchers have investigated the relative or unique associations between these two types of engagement and achievement (Alexander et al., 1993). Recently, researchers (Miles & Stipek, 2006; Trzesniewski et al., 2006) have speculated that the often found association between antisocial or aggressive conduct and achievement may be due to a "third variable" related both to aggression and achievement, such as cognitive self-control or self-regulated learning behaviors. To the extent that measures of conduct and self-regulated (i.e., effortful) engagement are correlated, the third variable explanation is more plausible. In samples of primary-grade children, Ladd et al. (1999) reported a correlation of .64 between cooperative participation and self-regulated participation, and Normandeau and Guay (1998) reported a correlation of  $-.51$  between aggressive behavior and cognitive self-control, a construct similar to effortful engagement. In their longitudinal study, Normandeau and Guay (1998) found that the effect of conduct engagement in kindergarten on grades 1 year later was accounted for by the effect of conduct engagement on teacher-rated cognitive self-control (e.g., the student sticks to what he or she is doing until finished, persists in face of failure, has to be reminded several times to do something before doing it). On the basis of these findings and the reasoning that effortful engagement in school

learning is more directly related to student mastery of subject matter content than is conduct engagement, we expected that only effortful engagement would uniquely predict subsequent achievement.

### Effect of TSRQ on Effortful Engagement

Researchers have drawn from diverse theoretical conceptualizations in explaining the processes that account for the effect of TSRQ on students' effortful engagement and achievement. On the basis of attachment theory perspectives (Bowlby, 1980), a close and supportive relationship with one's teacher would be expected to promote a child's emotional security and confidence. A secure relationship with the teacher may serve as a resource that permits young students to actively explore their environment and to cope more effectively with novel academic and social demands (Howes et al., 1994; Pianta & Steinberg, 1992). Drawing from this reasoning, Little and Kobak (2003) expected and found that among elementary children, emotional security with the teacher attenuated children's stress reactivity to negative teacher and peer events in the classroom.

Also on the basis of parenting and motivational literature, children who experience warm and close parent-child relationships are more motivated to please their parents and more likely to internalize their parents' values (Dix, 1991; Grusec & Kuczynski, 1997). In a short-term longitudinal study of children in Grades 3-5, teacher support predicted students' liking for school and buffered children with externalizing problems from becoming disaffected with school (Gest et al., 2005). Presumably, children who experience warm and close relationships with their teachers are more likely to identify with school and invest in the school's agenda. Finally, literature on the development of self-regulation (Eisenberg et al., 2005) also supports the view that TSRQ influences children's attention and self-regulation in the classroom. A negative teacher-student relationship might elicit negative emotions in children that interfere with attention and self-regulation (Blair, 2002), whereas a supportive teacher-student relationship might elicit positive moods that promote effective problem solving, regulation, and interactions with others (Isen, Daubman, & Norwicki, 1987; Pianta, 2006).

### Reciprocal Effects Among TSRQ, Effortful Engagement, and Achievement

Consistent with transactional models of development (Sameroff, 1975, 1989), we believe achievement in the early grades is the result of the unfolding of reciprocal processes, such that children's engagement both influences and is influenced by TSRQ and academic competencies. Previous researchers have demonstrated an effect of student antisocial conduct on TSRQ (Birch & Ladd, 1997, 1998; Ladd et al., 1999; Pianta & Steinberg, 1992; Pianta & Stuhlman, 2004). Similarly, it is reasonable to expect that teachers will also find it easier to show support and affection to students who try hard and attend to instructions. It is also likely that children's academic achievement affects, and is affected by, their effortful engagement. For example, Miles and Stipek (2006) found that poor literacy skills in first grade predicted antisocial conduct in third grade. Also supportive of the view that academic performance affects classroom engagement is the finding that academi-

cally focused interventions result in improvements in conduct as well as academic skills (Ayllon & Roberts, 1974; Coie & Krehbiel, 1984).

### Study Hypotheses and Approach

The primary purpose of this study was to test an indirect model of the effects of TSRQ on reading and math achievement via the direct effect of TSRQ on effortful engagement over a 3-year period (beginning when children were in first grade). As Cole and Maxwell (2003) asserted, "a fundamental requirement for one variable to cause another is that the cause must precede the outcome in time" (p. 559). Thus, in testing mediational models with structural equation modeling (SEM), the researcher would ideally collect data on the cause, the mediator, and effect at each of three or more time points (or waves). Such a design not only permits strong assumptions about indirect effects but also permits testing of stationarity and stability of effects, lag effects, and reciprocal causal pathways across children's first 3 years of postkindergarten education.

*Stationarity* implies that the degree to which one set of variables produces change in another set remains the same over time. Perhaps TSRQ in first grade is more important to engagement in Year 2 than TSRQ in Year 2 is to engagement in Year 3. A finding of stronger structural relations between TSRQ and engagement earlier versus later in students' first 3 years of school would be consistent with the view that the quality of children's relationships with their teachers at the beginning of their formal schooling sets in motion patterns of engagement that quickly become self-sustaining. *Stability of effects* refers to the degree to which the within-wave correlations are of the same magnitude at different points in development. *Lag effects* refers to the direct effects of Year 1 variables on Year 3 variables, above the year-to-year stability in the variables. For example, perhaps children's relationships with their first-grade teachers continue to influence their social relatedness with future teachers, above the year-to-year stability in teacher relatedness. Finding such a lag effect for TSRQ would be consistent with the view that children's early relationships with teachers are carried forward as mental representations (Bretherton, 1985) to subsequent relationships with teachers and might explain, in part, the long-term prediction of achievement on the basis of TSRQ in first grade (Pallas, Entwistle, Alexander, & Cadigan, 1987).

The decision to test separate models with reading and math achievement as outcomes instead of using a latent or a composite measure of achievement was based on previous findings that behavior problems predicted reading achievement more strongly than math achievement (Adams, Snowling, Hennessy, & Kind, 1999; DuPaul et al., 2004; Joussemet, Koestner, Lokes, & Landry, 2005). Additionally, because much more time is spent in literacy than in math instruction in early elementary classrooms (National Institute for Child Health and Human Development Early Child Care Research Network, 2003), TSRQ and child engagement might be more predictive of reading than of math achievement.

We also tested whether gender or ethnicity moderated the structural relations in the SEM. Some researchers have found that minority and/or low-socioeconomic status children (Burchinal et al., 2002; Meehan, Hughes, & Cavell, 2003) and boys (Skinner et al., 1998) benefited more from a supportive teacher-student rela-

tionship than did majority children or girls. Other researchers, however, have found no evidence that these demographic variables moderate the relationship between TSRQ and child outcomes (Pianta & Stuhlman, 2004; Silver, Measelle, Armstrong, & Essex, 2005).

We investigated these questions in a culturally and linguistically diverse sample of academically at-risk first-grade children. Children were deemed academically at risk on the basis of scoring below their school district median on a measure of literacy given at the beginning of first grade. Children with relatively low literacy skills in first grade are likely to experience more relational and academic stressors (Ladd et al., 1999; A. J. Reynolds & Bezruczko, 1993). When provided a supportive teacher presence, these children are expected to cope better with stressors and to participate more actively and appropriately in classroom activities, consequently gaining more in achievement. For these reasons, students with low literacy skills represent a population of considerable importance with respect to the effect of teacher support on children's behavioral engagement and academic achievement.

Previously published findings with this longitudinal sample have reported associations between TSRQ, effortful engagement, and achievement using two waves of data (Hughes & Kwok, 2006, 2007). Hughes and Kwok (2006) also reported a mediating role for TSRQ in accounting for the association between students' African American status and effortful engagement. The current study extends these findings by assessing each construct at each of three waves (years) of data, which permits a strong test of mediation, reciprocal effects, and stationarity and stability of effects. Additionally, the current study investigates the unique effects of two types of behavioral engagement, conduct and effortful engagement, on achievement.

## Method

### Participants

Participants were drawn from a larger sample of children participating in a longitudinal study examining the impact of grade retention on academic achievement. Participants were recruited from three school districts in Texas (one urban and two small city) across two sequential cohorts in first grade during the fall of 2001 and 2002. The composition of the urban school was 41% White non-Hispanic, 37% economically disadvantaged, and 11% limited English proficient. Enrollment of one of the small city schools was 40% White non-Hispanic, 61% economically disadvantaged, and 11% limited English proficient. The enrollment of the second small city school was 69% White non-Hispanic, 24% economically disadvantaged, and 5.2% limited English proficient. Children were eligible to participate in the longitudinal study if they scored below the median on a state-approved, district-administered measure of literacy; spoke either English or Spanish; were not receiving special education services; and had not been previously retained in first grade. School records identified 1,374 children as eligible to participate. Because teachers distributed consent forms to parents via children's weekly folders, the exact number of parents who received the consent forms cannot be determined. Incentives, in the form of small gifts to children and the opportunity to win a larger prize in a drawing, were instrumental in

obtaining 1,200 returned consent forms, of which 784 (65%) provided consent.

Analyses on a broad array of archival variables, including performance on the district-administered test of literacy (standardized within district, because of differences in test used), age, gender, ethnicity, eligibility for free or reduced-price lunch, bilingual class placement, cohort, and school context variables (i.e., percentage ethnic/racial minority, percentage economically disadvantaged), did not indicate any difference between children with and without consent. Although we cannot rule out differences between consenters and nonconsenters on variables not included in our data, we can conclude that the resulting sample of 784 participants (52.6% male) closely resembles the eligible sample on demographic and literacy variables relevant to students' educational performance. Of the 784 recruited children, 350 (44.6%) had complete data on all analysis variables assessed at all three occasions (i.e., first grade and 1 and 2 years later), and 671 (85.6%) had data on at least one of the analysis variables at each occasion. Attrition analyses showed that the 350 children with complete data did not differ from the 434 without complete data on demographic variables or study variables at baseline, which supports the assumption that data were missing at random. The overall rate of missingness for the 671 participants with some data at each assessment wave was 12.7%. The 671 participants did not differ from the remaining 113 participants on demographic or study variables at baseline. On the basis of these findings, we imputed the missing value based on these 671 children using SAS PROC MI.

Of these 671 participants, 356 (53.1%) were male, and the racial/ethnic composition was 34.9% White, 36.7% Hispanic, 23.5% African American, and 4.9% Asian/Pacific Islander. At entrance to first grade, children's mean age was 6.57 ( $SD = 0.38$ ) years. Children's mean score for intelligence as measured with the Universal Nonverbal Intelligence Test (McCallum & Bracken, 1997) was 92.89 ( $SD = 14.43$ ). On the basis of family income, 58.0% of participants were eligible for free or reduced-price lunch. For 35.1%, the highest educational level in the household was a high school certificate or less. The ethnic/racial composition for the 337 teachers (94.1% female) completing the teacher questionnaires was 81.3% White, 14.5% Hispanic, 2.7% African American, and 1.5% other ethnicities. The mean teaching experience was 4.42 years ( $SD = 1.82$ ), and 100% of teachers held teacher certification. All teachers had at least a bachelor's degree; 57.6% had done at least some graduate work.

### Design Overview

Assessments were conducted annually for 3 years, beginning when participants were in first grade. Teacher questionnaires assessing teachers' perceptions of the student-teacher relationship and of child engagement were administered in the spring of each year. Teachers received \$25 for completing and returning the questionnaires. Measures of math and reading achievement were individually administered at school at varying times during the school year, with the constraint that at least 8 months separated each annual assessment.

### Measures

**Academic achievement.** The Woodcock-Johnson III (WJ-III) Tests of Achievement (Woodcock, McGrew, & Mather, 2001) is

an individually administered measure of academic achievement for individuals 2 years of age to adulthood. The WJ-III Broad Reading age standard scores (Letter-Word Identification, Reading Fluency, and Passage Comprehension subtests) and the WJ-III Broad Math age standard scores (Calculations, Math Fluency, and Math Calculation Skills subtests) were used. Extensive research documents the reliability and construct validity of scores on the WJ-III and its predecessor (Woodcock & Johnson, 1989; Woodcock et al., 2001).

The Bateria Woodcock-Muñoz: Pruebas de Aprovechamiento—Revisada (Bateria-R; Woodcock & Muñoz-Sandoval, 1996) is the comparable Spanish version of the Woodcock-Johnson Tests of Achievement—Revised (Woodcock & Johnson, 1989), the precursor of the WJ-III. If children or their parents spoke any Spanish, children were administered the Woodcock-Muñoz Language Test (Woodcock & Muñoz-Sandoval, 1993) to determine the child's language proficiency in English and Spanish and selection of either the WJ-III or the Bateria-R. The Woodcock Compuscore (Woodcock & Muñoz-Sandoval, 2001) program yields scores for the Bateria-R that are comparable to scores on the Woodcock-Johnson Tests of Achievement—Revised. The Broad Reading and Broad Mathematics WJ-III scores were used in this study.

**Effortful engagement.** The teacher-report, 10-item effortful engagement scale was composed of 8 items from the Conscientiousness scale of the Big Five Inventory (John & Srivastava, 1999) and 2 items taken from the Social Competence Scale (Conduct Problems Prevention Research Group, 2004) that were consistent with our definition of academic engagement (effort, attention, persistence, and cooperative participation in learning). Although the Big Five Inventory is conceptualized as a measure of personality traits, the selected items from the Conscientiousness scale are similar to items used by other researchers to assess academic engagement (Ladd et al., 1999; Ridley, McWilliam, & Oates, 2000). Items were rated on a 1–5 Likert-type scale. The internal consistency of these 10 items for our sample was .95.

**Conduct engagement.** The teacher-rated measure of conduct (antisocial) engagement was derived from a 24-item questionnaire adapted from the California Child Q-Sort, a language-simplified personality inventory for use by nonprofessionals (Caspi, Block, Block, & Klopp, 1992). Our modification involved use of a rating scale versus Q-sort methodology and a reduction in the number of items from 100 to 24. These 24 items were selected on the basis of previous research demonstrating that they were consistently rated as prototypical of children with high levels of impulsivity and externalizing behaviors (Funder, Block, & Block, 1983). All items were rated on a 1–5 Likert scale.

We applied a cross-validation approach to examine the underlying structure because of the unclear factor structure of the measure (B. Thompson, 2004). The Year 1 data set ( $n = 344$ ) was randomly split into two even halves. We performed an exploratory factor analysis using principal-axis factoring with Promax rotation for the first half of the data; this resulted in a 15-item measure with four factors (9 items were deleted because of high cross-loadings). We then cross-validated the factor structure found from this analysis by performing confirmatory factor analysis on the second half data. Results of the confirmatory factor analysis confirmed the four-factor model,  $\chi^2(112, n = 339) = 225.7, p < .001$  (comparative fit index [CFI] = .97, root-mean-square error of approximation [RMSEA] = .05, standardized root-mean-square residual [SRMR] = .04), and this four-factor model fitted a second sample

adequately,  $\chi^2(112, n = 301) = 241.0, p < .001$  (CFI = .96, RMSEA = .06, SRMR = .05). The four factors were as follows: Prosocial, Antisocial, Ego Resiliency, and Ego Brittle. Model fit was invariant across cohorts and across Waves 1 and 2. Because the Prosocial (4 items;  $\alpha = .93$ ) and Antisocial (4 items;  $\alpha = .86$ ) scales were strongly correlated (standardized path coefficient = .90), we computed a single conduct scale as the mean of the Antisocial and Prosocial (reverse coded) scales. Example Prosocial items included “considerate and thoughtful” and “gets along well with other children.” Example Antisocial items included “physical or verbal aggression” and “tries to take advantage of others.”

*Teacher-reported teacher–student relationship:* The 22-item Teacher Student Relationship Inventory (TSRI; Hughes, Cavell, & Willson, 2001) is based on the Network of Relationships Inventory (Buhrmester & Furman, 1987). Teachers indicate on a 5-point Likert-type scale their level of support (16 items) or conflict (6 items) in their relationships with individual students. An exploratory factor analysis using principal-axis factoring with Promax rotation on 335 first-grade participants from the second cohort suggested three factors: Support (13 items), Intimacy (3 items), and Conflict (6 items). Results of confirmatory factor analysis on 449 first-grade participants from the first cohort found that the three-factor model provided an adequate fit for the data,  $\chi^2(204) = 697.803, p < .001$  (CFI = .92; RMSEA = .074). Furthermore, the null hypothesis of factor invariance across cohorts and times could be retained at the .01 level. Because the Intimacy scale was deemed less relevant to TSRQ, only the Support and Conflict scales were used in the current study. Example Support scale items ( $\alpha = .94$ ) included “I enjoy being with this child,” “This child gives me many opportunities to praise him or her,” and “This child talks to me about things he/she doesn’t want others to know.” Example Conflict scale items ( $\alpha = .91$ ) included “This child and

I often argue or get upset with each other” and “I often need to discipline this child.” In a longitudinal study of behaviorally at-risk elementary students, the TSRI predicted changes in behavioral adjustment and peer relationships (Meehan et al., 2003).

Results

Sample Descriptive Statistics and Intercorrelations

Using multiple imputation, we generated five complete data sets. For simplicity, the sample statistics are reported only for the first data set. Table 1 presents means and standard deviations for analysis variables broken down by gender and ethnicity. Table 2 presents the correlations among the analysis variables. For all the five imputed data sets, we used Green’s (1992) SEM approach to examine the stability of the within-wave correlations across the assessment periods. Green’s method is an SEM-based method to test whether correlation matrices are different from each other for either independent or dependent samples. We tested two models. Model 1 was an unconstrained model in which the within-wave correlations were freely estimated. Model 2 was a constrained model in which the within-wave correlations were constrained to be equal across waves. Then we conducted a chi-square difference test to test whether Model 2 was significantly worse than Model 1. The result was nonsignificant, indicating that we could assume the within-wave correlations were equal across waves. All within-wave correlations were invariant over time for the reading and math models.

Gender and Ethnic Differences

Significant gender differences were found on the measured variables on the basis of the results of one-way multivariate

analysis of variance. Over the five imputed data sets, the average  $F(17, 653)$  was 7.01 with a standard deviation of 0.35, and the significance value was less than .01. Girls performed better than boys on TSRI Support: for Year 1,  $F(1, 669) = 13.01$  ( $SD = 2.91$ ),  $p < .001$  ( $ES = .28$ ); for Year 2,  $F(1, 669) = 18.23$  ( $SD = 1.80$ ),  $p < .001$  ( $ES = .33$ ); and for Year 3,  $F(1, 669) = 13.67$  ( $SD = 2.79$ ),  $p < .001$  ( $ES = .28$ ). Girls also outperformed boys on TSRI Conflict: for Year 1,  $F(1, 669) = 33.16$  ( $SD = 5.60$ ),  $p < .001$  ( $ES = .44$ ); for Year 2,  $F(1, 669) = 31.54$  ( $SD = 4.15$ ),  $p < .001$  ( $ES = .43$ ); and for Year 3,  $F(1, 669) = 47.85$  ( $SD = 4.97$ ),  $p < .001$  ( $ES = .53$ ). In addition, girls scored higher than boys on effortful engagement: for Year 1,  $F(1, 669) = 40.36$  ( $SD = 1.68$ ),  $p < .001$  ( $ES = .49$ ); for Year 2,  $F(1, 669) = 29.86$  ( $SD = 2.97$ ),  $p < .001$  ( $ES = .42$ ); and for Year 3,  $F(1, 669) = 38.08$  ( $SD = 3.76$ ),  $p < .001$  ( $ES = .48$ ). Finally, girls outperformed boys on conduct engagement: for Year 1,  $F(1, 669) = 13.73$  ( $SD = 2.35$ ),  $p < .001$  ( $ES = .29$ ); and for Year 2,  $F(1, 669) = 13.87$  ( $SD = 1.17$ ),  $p < .001$  ( $ES = .29$ ). Girls also had higher reading scores at Time 1,  $F(1, 669) = 10.86$  ( $SD = 0.25$ ),  $p < .004$  ( $ES = .22$ ).

Significant racial/ethnic differences were also found on the measured variables. The average  $F(17, 653)$  was 7.49 with a standard error of 0.13, and the significance value was less than .01. Caucasian students performed better on the Time 3 reading test,  $F(1, 669) = 16.82$  ( $SD = 0.72$ ),  $p < .001$  ( $ES = .32$ ), and on math tests at all three time points: for Year 1,  $F(1, 669) = 82.29$  ( $SD = 1.55$ ),  $p < .001$  ( $ES = .70$ ); for Year 2,  $F(1, 669) = 72.99$  ( $SD = 2.93$ ),  $p < .001$  ( $ES = .66$ ); and for Year 3,  $F(1, 669) = 51.92$  ( $SD = 1.13$ ),  $p < .001$  ( $ES = .55$ ).

### Measurement Model for TSRQ

Confirmatory factor analyses were used to examine the factor structure for a teacher-only report of TSRQ ( $N = 671$ ). The latent construct of TSRQ at each occasion was indicated by the TSRI Support and Conflict scales. The items of the Conflict scale were

reverse coded so that a high score indicated low conflict between students and their teachers. To account for the dependency among observations (students) within clusters (classrooms), we conducted all analyses using the “complex analysis” feature in Mplus (Version 3.13; Muthén & Muthén, 2004), in which the models were estimated via the maximum likelihood estimation method with robust standard errors (Muthén & Muthén, 2004). The model fitted the data adequately, with the average  $\chi^2(7) = 32.54$  ( $SD = 8.52$ ),  $p < .01$ , the average CFI = .98 ( $SD = .01$ ), the average RMSEA = .07 ( $SD = .01$ ), and the average SRMR = .03 ( $SD = .004$ ). All the model estimated loadings were significant in a positive direction.

We also examined the invariance of factor loadings of the TSRQ model over time by comparing the chi-square statistics between models with and without constraining the factor loadings of the same indicators to be equal across waves. The difference in chi-square was not significant,  $\Delta\chi^2(2) = 0.36$ ,  $p = .83$ , suggesting that the relations between the two indicators and the latent construct were invariant over time. On the basis of the above time-invariant model, we further examined the factor loading invariance of the TSRQ model between different gender and ethnic groups using the multiple-group comparison approach under the SEM framework. The chi-square difference was significant between different gender groups,  $\Delta\chi^2(1) = 6.21$ ,  $p = .01$ . The average standardized factor loadings of TSRI Conflict and TSRI Support were .90 and .67, respectively, for the girls across waves and .92 and .63, respectively, for the boys across waves. Despite a statistically significant chi-square difference test, the magnitudes of the factor loadings were highly similar for boys and girls, which suggested that the construct of TSRQ was still comparable for girls and boys. There was no significant chi-square difference between different ethnic groups,  $\Delta\chi^2(1) = 0.001$ ,  $p = .98$ , which suggests that the pattern of relations between the two indicators and the latent construct was no different between the majority and minority students.

After taking stationarity into consideration, we obtained a simpler model (i.e., a model with more degrees of freedom because the paths were constrained to be the same across time) that fitted the data equally well, with average  $\chi^2(53) = 239.79$  ( $SD = 12.56$ ),  $p < .001$ , average CFI = .96 ( $SD = .003$ ), average RMSEA = .07 ( $SD = .002$ ), average SRMR = .07 ( $SD = .002$ ). The model with parameter estimates is shown in Figure 2. To provide a clear picture of the major findings, we did not include the covariance estimates between the exogenous variables and the covariance estimates between the residuals within and across waves in Figure 2 but present these estimates in Table 3. In Figure 2, all the unstandardized parameter estimates and the standardized estimates (presented in the parentheses) were the average values over the five imputed data sets. The unstandardized parameter estimates were tested according to the method developed by Schafer (1997). Nonsignificant paths are indicated by the dashed lines in the figure.

To test the effect of Time 1 TSRQ on Time 3 math achievement mediated by Time 2 effortful engagement, we adopted the method developed by MacKinnon, Lockwood, and Williams (2004) to calculate the confidence interval for the mediation effect. If the confidence interval does not include zero, the mediation effect is significant at  $p < .05$ . The point estimate of the mediation effect was .45; the 95% confidence interval of the target mediation effect (i.e., TSRQ at Year 1  $\rightarrow$  engagement at Year 2  $\rightarrow$  math at Year 3; confidence interval = .22, .75) indicated that this mediation effect was significant. The direct effect between TSRQ at Year 1 and math at Year 3 became nonsignificant after we included engagement at Year 2 in the model, which implies that the effect of teacher student-relationship on math achievement was fully me-

diated through effortful engagement. To obtain an effect size estimate of the mediation effect, we calculated the change in squared multiple correlation for the model with and without the two paths that constituted the mediation effect ( $\Delta R^2 = .01$ ). The effects of conduct engagement on math (i.e., conduct engagement at Year 1  $\rightarrow$  math at Year 2; conduct engagement at Year 2  $\rightarrow$  math at Year 3) were not significant.

**Reading achievement.** We repeated the above analyses with the reading achievement model and found a very similar pattern of results. The final model as presented in Figure 3 fitted the data adequately, with average  $\chi^2(52) = 218.46$  ( $SD = 12.50$ ),  $p < .001$ , average CFI = .96 ( $SD = .003$ ), average RMSEA = .07 ( $SD = .003$ ), and average SRMR = .06 ( $SD = .004$ ). Note that covariance estimates between exogenous variables and covariance estimates between the residuals within and across waves are presented in Table 4. The effect of Time 1 TSRQ on Time 3 reading achievement was fully mediated through Time 2 effortful engagement (point estimate = .57; 95% confidence interval of the mediation effect = .27, .93). To obtain an effect size estimate of the mediation effect, we calculated the change in squared multiple correlation for the model with and without the two paths that constituted the mediation effect ( $\Delta R^2 = .10$ ). As was the case for math, the effects of conduct engagement on math (i.e., conduct engagement at Year 1  $\rightarrow$  math at Year 2; conduct engagement at Year 2  $\rightarrow$  math at Year 3) were not significant.

### Moderators

We also examined the possible moderation effects by gender and ethnicity on the transactional relationships among teacher-student relationship, effortful engagement, and achievement. Multiple-group comparison showed that the effects of prior variables on later variables in Figure 2 (i.e., math) and Figure 3 (i.e., reading) were the same for boys and girls: math,  $\Delta\chi^2(15) = 23.74$ ,  $p = .07$ ; reading,  $\Delta\chi^2(16) = 25.09$ ,  $p = .07$ . An examination of the standardized path coefficients confirmed that the structural paths were highly similar for boys and girls. Majority and minority students were also compared in terms of the structural relations, and no differences were found for either math or reading: math,  $\Delta\chi^2(15) = 15.66$ ,  $p = .41$ ; reading,  $\Delta\chi^2(16) = 9.75$ ,  $p = .88$ .

### Discussion

As predicted, the effect of first-grade TSRQ on reading and math achievement 2 years later was completely mediated by Year 2 effortful engagement. This study offers the strongest data yet for the mediating effect of effortful engagement in accounting for the effect of TSRQ on changes in students' achievement. The assessment of TSRQ, effortful engagement, and achievement at each of three time periods provides a strong basis for tests of mediation (Cole & Maxwell, 2003) because the design controlled not only for prior levels of the dependent variable but also for prior levels of the independent variable and the mediator. In the test of the effect of the independent variable on the mediator, prior levels of the mediator were also controlled. Additional strengths are the inclusion of a measure of conduct engagement to determine the unique effect of effortful engagement on achievement and the use of an individually administered measure of reading and math achievement that has strong psychometric properties, rather than teacher

Table 3  
Parameter Estimates of Covariance in the Model Presented in Figure 2

Parameter	Unstandardized estimate	Standardized estimate
Covariance of exogenous variables		
TSRQ1 with ENG1	0.57	.70
TSRQ1 with MATH1	1.66	.16
TSRQ1 with CON1	0.62	.95
ENG1 with MATH1	3.14	.21
ENG1 with CON1	0.56	.58
MATH1 with CON1	1.47	.12
Covariance of correlated residuals		
TSRQ2 with ENG2	0.37	.41
TSRQ2 with MATH2	0.42 <sup>†</sup>	.04
TSRQ2 with CON2	0.48	.61
ENG2 with MATH2	0.45 <sup>†</sup>	.03
ENG2 with CON2	0.40	.39
MATH2 with CON2	0.53 <sup>†</sup>	.05
TSRQ3 with ENG3	0.24	.38
TSRQ3 with MATH3	0.11 <sup>†</sup>	.01
ENG3 with MATH3	0.39 <sup>†</sup>	.04
TSRI-CON1 with TSRI-CON2	0.10	.10
TSRI-CON1 with TSRI-CON3	0.10	.10
TSRI-CON2 with TSRI-CON3	0.14	.14

Note. Estimates with a dagger are not significant at  $p = .05$ . TSRQ = teacher-student relationship quality; ENG = teacher perception of child academic engagement; MATH = Woodcock-Johnson III Broad Math age standard score; CON = conduct engagement; TSRI-CON = Teacher Student Relationship Inventory Conflict subscale (teacher perception of conflict).

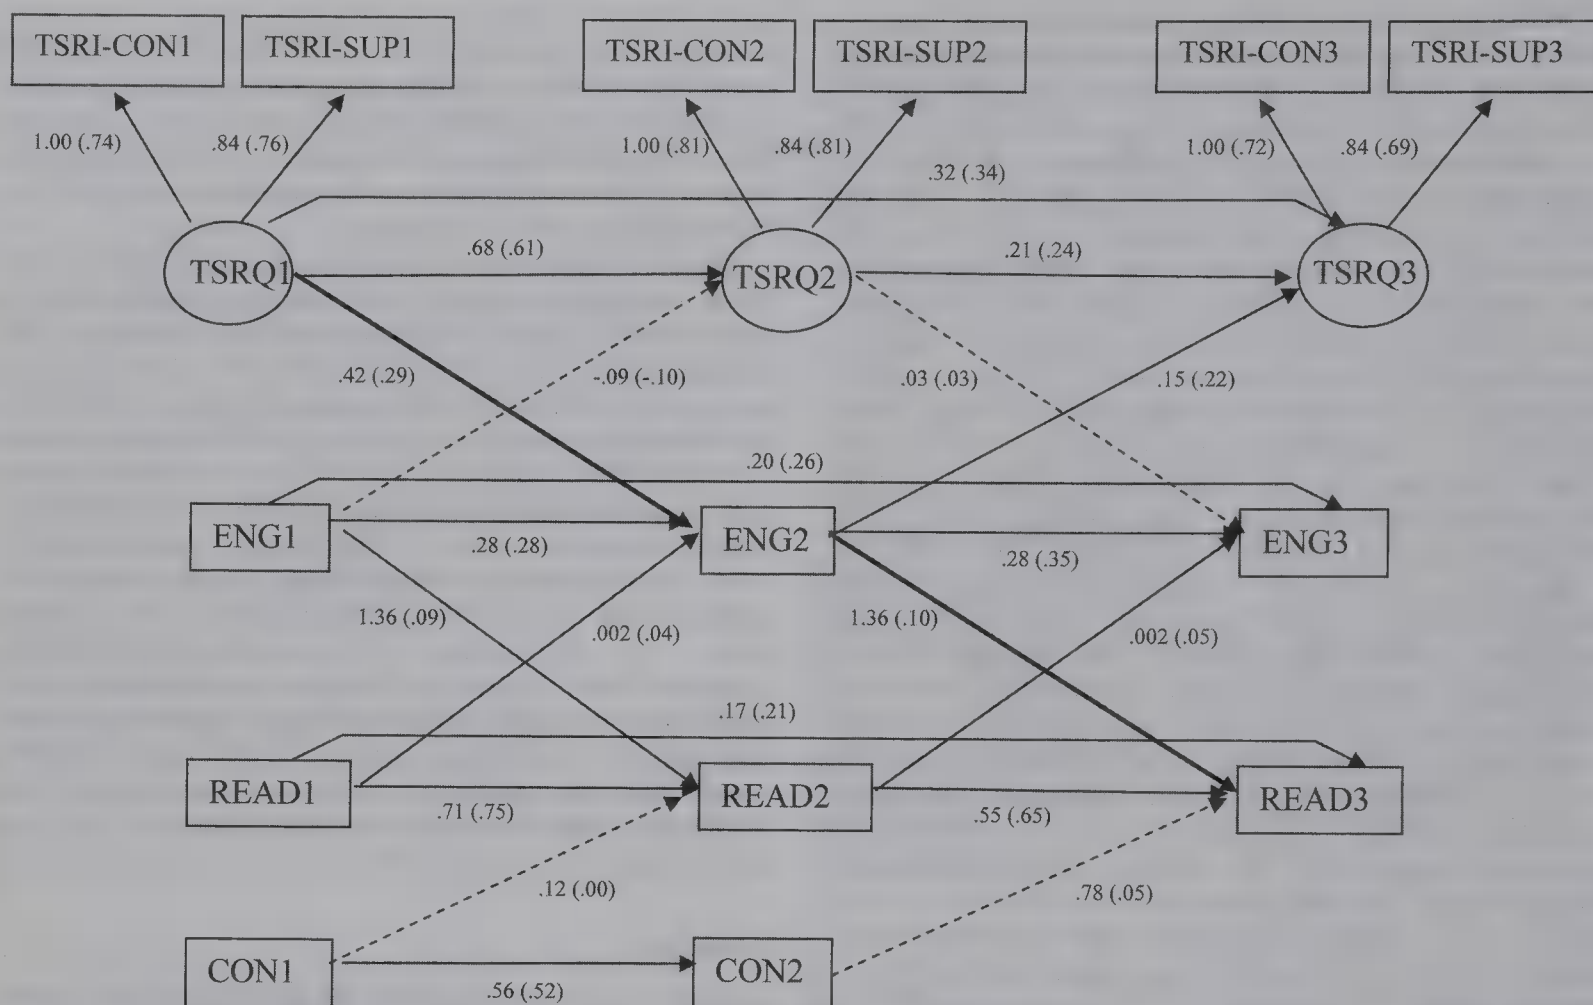

Figure 3. Model of reading achievement. The bold lines represent target indirect effects. The within-wave correlated residuals are not included in the figure for purposes of presentation clarity. Values are unstandardized parameter estimates, with standardized estimates in parentheses. TSRI-CON = Teacher Student Relationship Inventory Conflict subscale; TSRI-SUP = Teacher Student Relationship Inventory Support subscale; TSRQ = teacher-student relationship quality; ENG = effortful engagement; READ = reading performance; CON = conduct engagement.

report of student achievement or grades. The finding that results were nearly identical for models in which the outcome was reading and models in which the outcome was math suggests that the effects were robust across achievement domains. Despite main effects for gender and majority/minority ethnic status, effects were not moderated by gender or ethnicity. Thus, the pattern among these variables and the structural relations were similar for boys and girls and for majority and minority children.

The assessment of study variables at each of three time periods permits strong tests of bidirectional causal pathways. Not only were we able to control for previous levels of each variable in testing each direct effect, we also were able to test these pathways across two time periods. We found support for reciprocal effects between effortful engagement and TSRQ from Year 2 to Year 3 but not from Year 1 to Year 2. This finding might have been due to the higher level of stability for TSRQ from Year 1 to Year 2 than from Year 2 to Year 3.

Reciprocal effects of both math and reading achievement on effortful engagement were invariant across developmental periods. To our knowledge, this is the first study to investigate the effect of achievement on effortful engagement. Children with lower academic skills may become discouraged and believe that their aca-

ademic success is not attributed to their effort. One of the consequences of academic failure is learned helplessness, which is associated with low persistence and effort (Diener & Dweck, 1978). Researchers investigating the effect of achievement on antisocial behavior have speculated that children with low academic skills become frustrated and respond to their frustration with aggression (Miles & Stipek, 2006). Future research is needed to clarify the effect of achievement on different types of engagement and the processes that mediate the effect.

Evidence for stability of effects (e.g., year-to-year stability in measurement of the same construct) was found for effortful engagement and math achievement. However, the effect of Year 1 TSRQ on Year 2 TSRQ was stronger than the effect of Year 2 TSRQ on Year 3 TSRQ. This finding may be a result, in part, of the lag effect of Year 1 TSRQ on Year 3 TSRQ (see the discussion below). Although math demonstrated stability across years, the effect of Year 1 reading on Year 2 reading was stronger than the effect of Year 2 reading on Year 3 reading. Perhaps at older grades factors not included in our model become more important to reading performance.

As predicted, effortful engagement predicted achievement above the effects of prior levels of both conduct engagement and

Table 4  
Parameter Estimates of Covariance in the Model Presented in Figure 3

Parameter	Unstandardized estimate	Standardized estimate
Covariance of exogenous variables		
TSRQ1 with ENG1	0.57	.70
TSRQ1 with READ1	2.54	.19
TSRQ1 with CON1	0.62	.95
ENG1 with READ1	5.74	.29
ENG1 with CON1	0.56	.58
READ1 with CON1	2.77	.18
Covariance of correlated residuals		
TSRQ2 with ENG2	0.37	.41

TSRI-CON1 with TSRI-CON2	0.10	.10
TSRI-CON1 with TSRI-CON3	0.10	.10
TSRI-CON2 with TSRI-CON3	0.14	.14

*Note.* Estimates with a dagger are not significant at  $p = .05$ . TSRQ = teacher–student relationship quality; ENG = teacher perception of child academic engagement; READ = Woodcock–Johnson III Broad Reading age standard score; CON = conduct engagement; TSRI-CON = Teacher Student Relationship Inventory Conflict subscale (teacher perception of conflict).

achievement. Furthermore, the effect of effortful engagement on achievement was invariant across developmental periods for both reading and math. In contrast, conduct engagement did not contribute to achievement when prior levels of academic engagement and achievement were controlled. To our knowledge, this is the first longitudinal study to investigate the independent effects of these two types of classroom engagement on achievement. Both conduct engagement and effortful engagement probably have their origins in temperament-based self-regulatory competence (Blair, 2002; R. A. Thompson, 1999). Our results suggest that the aspects of self-regulatory competence that affect achievement are only those aspects that interfere with children's ability to attend to instruction and to persevere in academic tasks. These findings suggest that results from studies reporting predictive associations between antisocial behavioral styles and achievement (Miles & Stipek, 2006; Trzesniewski et al., 2006) might be explained by the association between antisocial behavior and constructs similar to our measure of academic engagement. If this is the case, interventions that target student conduct are unlikely to improve academic achievement unless they also improve student academic effort.

This study examined the development of the connections between effortful engagement, achievement, and teacher support in the same children in their first 3 years of formal schooling. Because children's achievement trajectories demonstrate greater stability after third grade (Miles & Stipek, 2006; Skinner et al., 1998), children's patterns of engagement and achievement formed in the first 3 years of formal schooling may have long-lasting impact on their future academic trajectories (Hamre & Pianta, 2001). The lag effect of Year 1 variables (TSRQ, effortful engage-

ment, and achievement) on the corresponding Year 3 variables is consistent with the view that children's early experiences in classrooms launch individual growth trajectories of engagement, achievement, and teacher relatedness. The launch effect may be smaller or disappear as year-to-year changes influence subsequent development. Taken together, these findings suggest that TSRQ in first grade shapes children's patterns of engagement in learning, which leads both to more supportive relationships with subsequent teachers and to higher levels of achievement. Additional years of data collection are needed to determine whether the structural relationships found in the first 3 years of formal schooling persist or whether the associations among teacher support, engagement, and achievement beyond Grade 3 are the result primarily of the stability of each construct.

These results need to be interpreted in the context of study limitations. Because these findings were obtained with a sample of children selected on the basis of scoring below their school district median on a test of early literacy, results may not generalize to children with higher literacy skills. However, the current sample is one of considerable concern to educators and policy makers, given that they scored in the bottom 50% of students in their school districts on a test of literacy. The sample was also ethnically diverse, with an overrepresentation of minority children (65%) relative to the composition of the schools from which these children were selected (58% minority). Thus, study findings point to the potential of interventions in primary grades for reducing racial and ethnic achievement disparities (Hughes & Kwok, 2007).

Another limitation of the study is its reliance on only teacher report for assessment of TSRQ. Initially we had intended to use a multi-informant latent construct of TSRQ based on the TSRI and a peer-nomination measure of teacher–student relationship support (Hughes & Kwok, 2007). Because this measurement model for TSRQ did not fit the data adequately,  $\chi^2(24) = 134.00$ ,  $p < .001$  (CFI = .84; RMSEA = .133; SRMR = .093), we resorted to the latent construct based on the two scales of the TSRI.

Finally, the lack of classroom observational data on teacher–student interactions means the mechanisms that account for the observed effect of TSRQ on students' effortful engagement are not clarified in this study. It may be that teachers who establish positive relationships with students differ in other ways that contribute to students' effort and persistence. For example, teachers who establish positive relationships with students may be more effective in structuring instruction or in managing classroom behavior (Hamre & Pianta, 2005).

As is often the case with longitudinal studies of community samples, missing data were a problem. However, several precautions were taken to ensure that results were not skewed by missing data. Attrition analyses supported the assumption that data were missing at random, and the overall level of missingness was low (12.7%). Furthermore, models estimated with data for those 350 participants who had complete data were nearly identical to results obtained with imputed data for the 671 participants with some data at each of the three waves.

It is well established that children who attend quality preschool programs begin their formal schooling with stronger academic and social skills (for a review, see R. Reynolds, Magnuson, & Ou, 2006). These domains operate in synergistic fashion, such that positive movement in one domain is likely to produce positive movement in other domains. The long-term benefit of such pro-

gram participation may be the result of reciprocal processes between achievement, academic engagement, and TSRQ. Thus, successful interventions at any point in this nexus of influences in the early grades may reverberate in ways that propel positive social and achievement trajectories, and interventions that target all three domains are especially likely to improve achievement.

# Interplay Between Personal Goals and Classroom Goal Structures in Predicting Student Outcomes: A Multilevel Analysis of Person–Context Interactions

Shun Lau and Youyan Nie  
Nanyang Technological University

This study examined cross-level interactions between personal goals and classroom goal structures, as well as their additive contributions to predicting math achievement, engagement, interest, effort withdrawal, and avoidance coping, using a sample of 3,943 Grade 5 students from 130 classrooms. Results of hierarchical linear modeling showed that classroom performance goal structures exacerbated (a) the negative association between personal performance-avoidance goals and engagement and (b) the positive relations of personal performance-avoidance goals to effort withdrawal and avoidance coping. Moreover, both classroom performance goal structures and personal performance-avoidance goals had maladaptive patterns of relations to outcomes at their respective levels of analysis, whereas classroom mastery goal structures and personal mastery goals showed adaptive relations. Our findings underscore the importance of a multilevel interactionist perspective in understanding achievement motivation and making recommendations for educational practices.

**Keywords:** classroom goal structure, personal goal orientation, person–context interaction, achievement goal theory, elementary school

In the achievement goal literature, two lines of research have received considerable attention. The first line of research reflects the *person* perspective of motivation and focuses on investigating the motivational dynamics of individuals who adopt different types of personal goals (Dweck, 1986; Dweck & Leggett, 1988; Elliot, 2005). The second line of research reflects the *contextualist* perspective and focuses on how different types of contextual goal structures (salient goal-related messages conveyed by classroom practices or school policies) influence achievement-related behavior in educational settings (Ames, 1992; Ames & Archer, 1988; Maehr & Midgley, 1996). Although the two perspectives are complementary and mutually informative (Roeser, 2004), relatively little research has integrated the person and contextualist perspectives to study motivational phenomena in achievement contexts (Linnenbrink, 2004, 2005). In this study, we examined the joint (additive and interactive) contributions of classroom goal

structures and personal goals to the prediction of students' achievement and motivational outcomes from a *multilevel interactionist* perspective. A specific emphasis of this article is a clear distinction between the personal and the contextual levels in our conceptualization and statistical analysis of person–context interactions (Chan, 2006; Glick, 1985; Raudenbush & Bryk, 2002).

## Person Perspective

For researchers who are oriented toward the person perspective, one of their primary objectives is to build a science of achievement motivation with achievement goals as the central organizing constructs (Dweck, 1986; Dweck & Leggett, 1988; Elliot, 2005; Pintrich, 2000). In educational settings, students' achievement goals represent their reasons or purposes for engaging in academic tasks. A large body of empirical evidence has been accumulated in relation to three types of personal goals:<sup>1</sup> (a) personal mastery goals, which emphasize learning new knowledge and improving one's skills; (b) personal performance-approach goals, which emphasize demonstrating one's competence relative to others; and (c) personal performance-avoidance goals, which emphasize the avoidance of showing one's incompetence relative to others. The general findings are that personal mastery goals and performance-avoidance goals are consistently associated with adaptive and maladaptive outcomes, respectively. However, empirical evidence

<sup>1</sup> In the latest formulation of achievement goal constructs, mastery goals were bifurcated into mastery-approach and mastery-avoidance goals (Elliot & McGregor, 2001; Pintrich, 2000). In this article, we focused on the approach dimension of the mastery goal and both the approach and avoidance dimensions of the performance goal because these three personal goals have produced the most solid empirical base.

for the role of performance-approach goals in achievement-related outcomes is mixed (see Elliot, 2005; Harackiewicz, Barron, Pintrich, Elliot, & Thrash, 2002; Midgley, Kaplan, & Middleton, 2001; Pintrich & Schunk, 2002, for recent reviews).

### Contextualist Perspective

In a parallel development, practice-oriented and reform-minded researchers who are oriented toward the contextualist perspective have turned their attention to the influences of contextual (classroom or school) goal structures on students' achievement motivation (Ames, 1992; Ames & Archer, 1988; Anderman, Maehr, & Midgley, 1999; Maehr & Midgley, 1996; Roeser, 2004). One of their primary concerns is to identify contextual factors that are systematically related to key educational outcomes. Much research has focused on two types of classroom goal structures derived from the achievement goal theory: (a) the classroom mastery goal structure and (b) the classroom performance goal structure.<sup>2</sup> In mastery-oriented classrooms, instructional practices, task assignment, and evaluation procedure are structured to emphasize learning, task mastery, and trying hard to improve one's skills. In contrast, in performance-oriented classrooms, instructional practices, task assignment, and evaluation procedure are structured to emphasize demonstrating competence. The general findings are that classroom mastery goal structures are related to adaptive outcomes and classroom performance goal structures are related to maladaptive outcomes, although variations exist depending on the specific outcomes under investigation (see Kaplan, Middleton, Urdan, & Midgley, 2002; Meece, Anderman, & Anderman, 2006; Urdan, 2004, for recent reviews).

### Level of Analysis Problem

Although research based on the person and contextualist perspectives has yielded different types of information (the former about motivational dynamics of individuals with different profiles of personal goals; the latter about what classroom or school environments would enhance or impede students' learning and motivation), considerable confusion has arisen from attempts to make substantive conclusions about influences of contextual goal structures by using evidence derived from the personal level of analysis (Roeser, 2004). Such confusion is exemplified by a recent debate that centered on the "unique positive potential of performance-approach goals, relative to mastery goals" (Harackiewicz, et al., 2002, p. 638; Midgley et al., 2001). Although the evidence that was marshaled to support each side of the debate was primarily based on the individual level of analysis, both Midgley et al. and Harackiewicz et al. discussed the broader educational implications of the evidence at the contextual level. For example, Midgley et al. were concerned about the unsettling implication that proving the adaptiveness of personal performance-approach goals might convey a message to teachers that they should emphasize performance goals in their classrooms—that "[t]he call for a reconceptualization of goal theory gives the message that it may be alright to emphasize the demonstration of ability and competition among students" (p. 83). In contrast, Harackiewicz et al. argued that emphasizing multiple goals in the classroom would provide students with multiple pathways to achieve the same valued outcomes—that "there may be multiple pathways to improve schools, not just one 'mas-

tery road' that all must travel" (p. 643). Thus, there seems to be an implicit assumption that what is true at the individual level of analysis is also true at the contextual level of analysis (Roeser, 2004).

In this article, we argue that person-level findings cannot be directly translated into conclusions at the contextual level and that direct evidence derived from the contextual level of analysis is required to appropriately inform classroom practices or school policies. Although evidence has been reported to show either the direct relations between contextual goal structures and student outcomes or the indirect relations mediated by personal goals (e.g., Church, Elliot, & Gable, 2001; Kaplan & Midgley, 1999; Nolen & Haladyna, 1990; Roeser, Midgley, & Urdan, 1996), the reliance on single-level analyses in many of the reported studies has created interpretive difficulty.

Conceptually, a variable takes on different meanings at different levels of analysis (Chan, 2006; Glick, 1985; Raudenbush & Bryk, 2002). In relation to achievement goal research, if a researcher's objective is to study the contextual effects of classroom goal structures on student outcomes, the level of conceptualization is the classroom and not the individual. Accordingly, in statistical analysis, classroom goal structures should be treated as level-2 variables. In contrast, if a researcher's objective is to study the psychological correlates of personal goals, the level of conceptualization is the individual and not the classroom. Accordingly, in statistical analysis, personal goals should be treated as level-1 variables, and the conclusion drawn from this level of analysis should only be applicable to level 1. Statistically, ignoring the nested structure of the data and reliance on single-level analysis can lead to misleading estimates of parameters (Cronbach, 1976; Raudenbush & Bryk, 2002; Snijders & Bosker, 1999).

### Are Person-Level Findings Consistent With Classroom-Level Findings?

Recent methodological advances in multilevel analysis or hierarchical linear modeling (HLM) have allowed researchers to analyze hierarchical data in a multilevel framework, thus resolving the level of analysis problem (Goldstein, 2003; Raudenbush & Bryk, 2002; Snijders & Bosker, 1999). The most relevant and informative studies are those that included both classroom goal structures and personal goals in the same HLM analysis. These studies have enabled direct comparisons between the role of classroom goal structures and personal goals with the same sample, measurement, and design characteristics. Moreover, they have provided evidence about the unique contribution of classroom goal structures after accounting for the predictive contribution of personal goals. This type of research, however, is limited in number and has yielded mixed findings. For example, Karabenick (2004) found that, in college introductory chemistry classrooms, level-1 (person-level) relations showed differential consistency with level-2 (classroom-level) relations, depending on the outcome variables used in the

<sup>2</sup> Some recent research has distinguished between the classroom performance-approach and classroom performance-avoidance goal structures (e.g., Kaplan, Gheen, & Midgley, 2002; Karabenick, 2004; Wolters, 2004), but the empirical support for such a distinction is not well established (see Discussion section for an elaboration of this point).

analysis. Specifically, at level 1, personal mastery and performance-approach goals were significant positive predictors of help-seeking approach, whereas personal performance-avoidance goals were significant negative predictors. At level 2, however, classroom mastery, performance-approach, and performance-avoidance goal structures were not significant predictors of help-seeking approach. When help-seeking avoidance was used as the outcome variable, level-1 relations were consistent with level-2 relations. Personal performance-avoidance goals were significant positive predictors at level 1 and classroom performance-avoidance goal structures were significant positive predictors at level 2. The other two personal goals and classroom goal structures were not significant predictors at level 1 and level 2, respectively. In another HLM study, Kaplan, Gheen, and Midgley (2002) found that level-1 and level-2 relations were quite consistent in a sample of Grade 9 students in math classrooms. Specifically, at level 1, personal mastery goals were negative predictors of disruptive behavior, whereas personal performance-approach and performance-avoidance goals were positive predictors. At level 2, classroom mastery goal structures were negative predictors of disruptive behavior, whereas classroom performance-approach goal structures were positive predictors.

Although these studies have significantly contributed to our understanding of multilevel relations, the paucity of research that included both classroom goal structures and personal goals in the same HLM analysis as well as the inconsistency of evidence has limited the generalizability of the findings to different outcomes and different age groups. Accordingly, one of the primary objectives of this study was to examine the predictive relations of classroom goal structures and personal goals to an expanded array of outcomes in Grade 5 math classrooms, including academic achievement, interest, engagement, effort withdrawal, and avoidance coping. The inclusion of both achievement and interest as outcomes is particularly pertinent in light of Harackiewicz et al.'s (2002) review of evidence in support of the differential relations that personal mastery goals were positively related to interest, but not achievement, whereas personal performance-approach goals were positively related to achievement, but not interest. Moreover, the inclusion of the three other outcome variables would allow us to examine the role of classroom goal structures and personal goals in both adaptive and maladaptive functioning of students. It is our aim that this study would capture the best features of the person and contextualist perspectives by advancing our knowledge of motivational dynamics at the student level as well as informing educational practices at the classroom level.

### From Additive Models to Interactive Models

In the preceding sections, we have discussed the rationale and evidence in support of moving from single-level analysis to multilevel analysis. The HLM research we have reviewed employed additive multilevel models to explore the unique contributions of classroom goal structures and person goals to predicting outcomes at different levels. Additive multilevel models assume that relations between level-1 variables (e.g., between personal goals and student-level outcomes) are homogenous across different contexts. This assumption needs to be tested explicitly in order to determine whether level-1 relations vary across classroom contexts and, if so, how classroom contexts may moderate (strengthen or weaken) the

relations at level 1. The multilevel interactionist framework would be most suitable for addressing these questions.

### Multilevel Interactionist Perspective

Consistent with the trend toward interactive models in developmental psychology (e.g., Bergman, Cairns, Nilsson, & Nystedt, 2000; Magnusson & Stattin, 1998), personality-social psychology (e.g., Mischel, 2003; Mischel & Shoda, 1995), educational psychology (e.g., Linnenbrink, 2004; Linnenbrink & Pintrich, 2001), and psychopathology (e.g., Ingram & Luxton, 2005; Rutter et al., 1997), we conceptualized students' achievement motivation in the classroom from an interactionist perspective. The specific kind of interaction we focus on in this article is termed multilevel (or cross-level) interaction, which is a form of statistical moderation (Baron & Kenny, 1986; Raudenbush & Bryk, 2002). A classroom context acts as a moderator if relations at the individual level vary as a function of the classroom context. In relation to achievement goal theory, a classroom goal structure acts as a moderator if it either strengthens or weakens the relations between personal goals and student outcomes. A theoretical significance of the interactionist perspective is that it provides a conceptual framework for researchers to investigate whether and how the motivational system of the individual may operate differently under varying contextual conditions, thus advancing our understanding of individuals' differential vulnerability to environmental stress and differential receptivity to environmental support (Wachs, 2000). An applied significance is that findings derived from interaction analyses not only provide teachers, policy makers, and educational reformers with important information about whether an intervention works in general, but also whether it works differentially for different types of students. Accordingly, another key objective of this study was to examine how classroom goal structures moderated the relations between personal goals and student outcomes.

Of particular relevance to our interest in studying person-context interaction are studies conducted by Newman (1998) and Linnenbrink (2005). In his experimental study, Newman (1998) manipulated the goal context and randomly assigned fifth and sixth graders to either a mastery or performance goal context. He found that in the performance goal context, personal performance-approach goals tended to be negatively related to help seeking, whereas in the mastery goal context, the relation tended to be positive.

Linnenbrink (2005) conducted a quasi-experimental study in which she measured Grade 6 students' entering personal goals (mastery and performance-approach goals) and manipulated classroom goal structures by providing participating teachers with specific suggestions for practice, primarily on the basis of the evaluation and recognition components of the TARGET system (Ames, 1992; Epstein, 1988). She included three classroom goal conditions in her analysis—mastery, performance-approach, and combined mastery/performance-approach. Using multivariate analysis of variance (MANCOVA), she found no significant interactions between classroom goal conditions and person goals, and therefore concluded that "students' entering personal goal orientations did not alter the way in which they responded to the classroom goal context" (p. 204). However, Linnenbrink (2005) did not include performance-avoidance goals in her study and neither did Newman (1998). It turns out, as we show in the

Analyses and Results section, that person–context interactions were especially salient between personal performance-avoidance goals and classroom performance goal structures. To provide a comprehensive account of the patterns of person–context interactions, this study extended previous work by including personal mastery, performance-approach, and performance-avoidance goals, and by using an alternative research design and analytic strategy to study person–context interactions.

### Hypotheses

To examine whether and how classroom goal structures moderate the relations between personal goals and student outcomes, we used HLM to test three hypotheses. The first is termed the *additive hypothesis*. This is a main effect<sup>3</sup> hypothesis in which classroom goal structures and personal goals have additive contributions to the prediction of student outcomes. Under this hypothesis, for example, classroom mastery goal structures would predict outcomes at the classroom level and personal mastery goals would predict student-level outcomes, but classroom mastery goal structures do not moderate the relations between personal mastery goals and student-level outcomes.

The second hypothesis is termed the *reinforcing hypothesis*, which includes two types of interaction. In the first type of reinforcing interaction, classroom goal structures strengthen a desirable relation at the individual level (an enhancing pattern). An example consistent with this type of interaction is that classroom mastery goal structures strengthen the desirable relation between personal mastery goals and interest. Another example is that classroom performance goal structures strengthen the desirable relation between personal performance-approach goals and achievement. This type of interaction can be linked to the matching (Linnenbrink, 2004, 2005) or the person–environment fit hypothesis (Eccles et al., 1993; Hunt, 1975) proposed in prior research. The matching hypothesis suggests that a classroom goal structure that affords opportunities for the pursuit of a personal goal (i.e., a match between the person and the context) would lead to adaptive outcomes. The concept of person–environment fit or goal congruence is also central to research in organizational psychology (Edwards, Cable, Williamson, Lambert, & Shipp, 2006) and vocational choices (Holland, 1997). For example, Holland (1997) proposed that people would perceive an occupational environment to be reinforcing and satisfying when environmental features resemble their own personal characteristics. This person–environment fit would result in stability of behavior because people would receive a substantial amount of selective reinforcement of their behavior in such an environment.

Another type of reinforcing interaction is that classroom goal structures strengthen an undesirable relation at the individual level (an exacerbating pattern). An example consistent with this type of interaction is that classroom performance goal structures strengthen the undesirable relation between personal performance-avoidance goals and avoidance behavior. This pattern of interaction is consistent with the vulnerability-stress hypothesis in psychopathology (Ingram & Luxton, 2005). Vulnerability refers to a personal characteristic that predisposes an individual to a psychological disorder and stress refers to an environmental factor that disrupts the normal functioning of an individual. The hypothesis states that the probability of developing a given disorder depends

on the interaction between the degree of personal vulnerability and the level of stress experienced by the individual (Ingram & Price, 2001; Monroe & Simons, 1991). Although the vulnerability-stress hypothesis is commonly used in the field of psychopathology, it provides insight into the understanding of the reinforcing exacerbating pattern in relation to personal performance-avoidance goals. The hypothesis suggests that students who strongly endorse performance-avoidance goals would be vulnerable to a goal context that emphasizes demonstrating competence and social comparison of ability. It is worth noting that despite the similarity (or “match”) between classroom performance goal structures and personal performance-avoidance goals, this type of interaction is expected to lead to maladaptive outcomes, thus it could not be explained by the person–environment fit or matching hypothesis, which generally implies an enhancing effect.

The third hypothesis is termed the *counterbalancing hypothesis*, which also includes two types of interaction. In the first type of interaction, classroom goal structures weaken a desirable relation at the individual level (a dampening pattern). An example consistent with this type of interaction is that classroom performance goal structures weaken the desirable relation between personal mastery goals and interest. Another example is that classroom mastery goal structures weaken the desirable relation between personal performance-approach goals and achievement. In these examples, the positive potential of an individual is dampened (or not fully realized) due to goal incongruence. This pattern of interaction is consistent with the notion of “mismatch” or “misfit” in the matching (Linnenbrink, 2004, 2005) or person–environment fit hypothesis (Eccles et al., 1993; Hunt, 1975).

Another type of counterbalancing interaction is that classroom goal structures weaken an undesirable relation at the individual level (a buffering pattern). An example consistent with this type of interaction is that classroom mastery goal structures weaken the undesirable relation between personal performance-avoidance goals and avoidance behavior. This pattern of interaction is consistent with the buffering hypothesis proposed in prior research (Linnenbrink, 2004, 2005). The buffering hypothesis suggests that a supportive environment can buffer the negative impact of personal vulnerability on achievement-related outcomes.

Overall, the additive, reinforcing, and counterbalancing hypotheses proposed in this study are able to incorporate the various types of relation between classroom goal structures and personal goals. In addition to their generality and comprehensiveness, a strength of these hypotheses is that they can be tested systematically and unambiguously by specific patterns of results in HLM. An example illustrating the links between these hypotheses and specific patterns of HLM results is presented in the Analyses and Results section.

### Objectives and Research Questions

In summary, a primary objective of this study was to examine the patterns of cross-level interactions between classroom goal

<sup>3</sup> To avoid awkward and cumbersome terminology, we used the term “effects” (e.g., main effects, interactive effects, additive effects, moderating effects) in a noncausal sense to refer to predictive relations in this article.

structures (mastery and performance) and personal goals (mastery, performance-approach, and performance-avoidance) in predicting multiple outcomes in a large sample of Grade 5 students in math classrooms. Another key objective was to examine the main (or additive) effects of classroom goal structures and personal goals on predicting student outcomes, if interactions were not significant or if the patterns of interactions were ordinal (Cohen, Cohen, West, & Aiken, 2003; Pedhazur, 1997).

We addressed the following research questions in this study: (a) Did classroom goal structures moderate the student-level relations between personal goals and outcomes? (b) If cross-level interactions (or moderating effects) were significant, would they show reinforcing or counterbalancing patterns? (c) If the interactions were not significant or displayed ordinal patterns of interactions, what would be the unique contributions of classroom goal structures and personal goals to predicting outcomes? (d) Were classroom-level relations between classroom goal structures and outcomes consistent with student-level relations between personal goals and outcomes?

## Method

### Participants

This study was part of a larger research project investigating the relations between learning environments and student outcomes. The participants in this study were 3,943 Grade 5 students from 130 classrooms in 38 elementary schools in Singapore. The sample included 2,754 Chinese (69.8%), 824 Malay (20.9%), 262 Indian (6.6%), and 103 students of other ethnic origins (2.6%). The gender distribution of the sample was 52.7% male and 47.3% female. The mean age of the participants was 11.4 years. English is the medium of instruction in Singapore, and all students formally start learning English in Grade 1.

### Sampling Design and Procedure

Low statistical power to detect interaction effects, especially in the presence of measurement errors, has been an issue of great concern (Aiken & West, 1991; Cohen et al., 2003; McClelland & Judd, 1993). Therefore, consideration of sampling design is especially important in testing interaction hypotheses. In this study, we sampled a large number of students and classrooms using a stratified random sampling technique. Schools were divided into three strata based on their prior aggregate school achievement and 13 schools were randomly selected from each stratum. One school dropped out of the study, leaving a total of 38 schools in the sample. About half of the Grade 5 classrooms in each participating school were randomly selected to do the math survey and assessment. Our sampling design ensured that we tapped sufficient "natural variance" of classroom characteristics and student demography by selecting schools and classrooms that covered a broad spectrum of achievement levels.

The procedure consisted of two parts. Part 1 was an online survey conducted in the 8th month from the beginning of the school year. The online survey included two forms. Half of the students in each class were randomly selected to complete survey Form 1, in which students reported their motivational beliefs and achievement-related behaviors in their math classrooms. The other

half of the students in the same class completed survey Form 2, in which students reported their perceived classroom goal structures. In other words, half of the students provided student-level (or level-1) data and the other half provided classroom-level (or level-2) data. In effect, half of the students served as independent raters of classroom goal structures. Because different groups of students provided data at different levels, potential inflation of cross-level interactions would be reduced. Such inflation could occur, for example, as a result of similar item wordings of the personal goal and classroom goal structure measures. The average numbers of students completing Forms 1 and 2 per class were 14.8 and 15.5, respectively. In Part 2 of the study, which was conducted about 1 month after the survey administration, a math achievement test was administered to all the students who had completed either Form 1 or Form 2 of the survey.

### Measures

All of the items on the survey were rated on 5-point Likert scales (1 = *strongly disagree* to 5 = *strongly agree* or 1 = *never* to 5 = *always*). Sample items of self-report scales are provided in the Appendix.

**Classroom goal structures.** Two types of classroom goal structures were assessed—classroom mastery and classroom performance goal structures. The classroom mastery goal structure describes an environment in which the teacher emphasizes that learning, task mastery, and working hard are important. The classroom performance goal structure describes an environment in which the teacher emphasizes that demonstrating high ability and getting better grades than other students are important. It is worth noting that our measure of the classroom performance goal structure focuses on the approach dimension. The measures of classroom mastery and classroom performance goal structures were adapted from the Patterns of Adaptive Learning Survey (PALS; Midgley et al., 2000).

A confirmatory factor analysis was conducted to examine the factor structure of the constructs. A two-factor structure provided a good fit for the data,  $\chi^2(26, N = 2017) = 239.61$ , Tucker-Lewis index (TLI) = .92, comparative fit index (CFI) = .95, root-mean-square error of approximation (RMSEA) = .06. Each scale showed adequate internal consistency ( $\alpha = .83$  for classroom mastery goal structure and  $\alpha = .73$  for classroom performance goal structure).

Classroom-level measures of classroom goal structures were derived from aggregating (i.e., averaging within each classroom) individual students' perceptions of classroom goal structures (Karabenick, 2004; A. M. Ryan, Gheen, & Midgley, 1998). These aggregated measures were used as level-2 predictors in HLM. The total variability of perceived classroom goal structures consisted of the within-class and between-class components. The aggregated measures we used reflect the between-class component.

**Personal goals.** Three types of personal goals were measured: personal mastery, personal performance-approach, and personal performance-avoidance goals. The personal mastery goal scale assessed students' desire to learn new things and to master challenging concepts in math. The personal performance-approach goal scale assessed students' desire to demonstrate their superior ability relative to their peers and to obtain favorable judgment from teachers. The personal performance-avoidance goal scale

assessed students' desire to hide their weaknesses in math and to avoid being perceived as incompetent by their teachers and peers. The measures of personal goals were adapted from PALS (Midgley et al., 2000).

A confirmatory factor analysis was conducted to examine the factor structure of the constructs. A three-factor structure provided an adequate fit for the data,  $\chi^2(62, N = 1926) = 707.91$ ,  $TLI = .91$ ,  $CFI = .94$ ,  $RMSEA = .07$ . Each scale showed adequate to high internal consistency ( $\alpha = .85$  for personal mastery goal,  $\alpha = .87$  for personal performance-approach goal, and  $\alpha = .72$  for personal performance-avoidance goal).

**Achievement.** A multiple-choice math achievement test was developed for this study because a standardized test of math achievement at Grade 5 was not available in Singapore. The test was intended to assess students' knowledge and skills in math at the Grade 5 level. It included four types of questions, which required understanding basic math concepts, performing routine procedures, using complex procedures, and solving novel problems. A panel of researchers and school teachers who had experience teaching math constructed and reviewed the items to ensure the content validity, clarity, and grade-level appropriateness of the assessment instrument in the local context. A pilot study was conducted to select items from the item pool on the basis of their psychometric quality such as item difficulty, item discrimination, and functioning of distractors. A final set of 27 items was selected and administered in this (main) study. To select items for final scoring, we adopted the criterion used in the Trends in Mathematics and Science Study 1999 (TIMSS 1999; Mullis & Martin, 2000). Four items that had an item discrimination index less than 0.2 were dropped. The 23 items that were used for final scoring had high reliability ( $\alpha = .87$ ). Standardized IRT (item response theory) scores were used in further analyses.

**Adaptive and maladaptive motivational outcomes.** Two adaptive and two maladaptive motivational outcomes were assessed in this study. The adaptive motivational outcomes included students' engagement and interest in math classes. Our measure of engagement was based on students' report of their attention, effort, and participation in their math classes (Steinberg, Lamborn, Dornbusch, & Darling, 1992; Wellborn & Connell, 1987). Our measure of interest was based on students' reports of their intrinsic motivation and enjoyment in their math classes (Elliot & Church, 1997). The maladaptive motivational outcomes included avoidance coping and effort withdrawal. The avoidance coping scale assessed students' tendency to give up when the work was difficult or boring. It was adapted from the Motivated Strategies for Learning Questionnaire (Pintrich, Smith, Garcia, & McKeachie, 1993). The effort withdrawal scale assessed students' tendency to hold back or minimize effort in their math work (Meece, Blumenfeld, & Hoyle, 1988; Nicholls, Patashnick, & Nolen, 1985).

A confirmatory factor analysis was conducted to examine the factor structure of the constructs. A second-order factor model, in which interest and engagement loaded onto the higher order factor of adaptive functioning and effort withdrawal and avoidance coping loaded onto the higher order factor of maladaptive functioning, provided a good fit for the data,  $\chi^2(99, N = 1926) = 552.89$ ,  $TLI = .96$ ,  $CFI = .97$ ,  $RMSEA = .05$ . Each scale showed adequate to high internal consistency ( $\alpha = .93$  for interest,  $\alpha = .74$  for engagement,  $\alpha = .80$  for effort withdrawal, and  $\alpha = .79$  for avoidance coping).

## Analyses and Results

### *Analytic Approach to Modeling Student Outcomes*

All predictors and outcome variables were standardized before running hierarchical linear modeling (HLM). Outcome variables and level-1 predictors were standardized at level 1. Standardized level-2 predictors were derived from first aggregating level-1 scores to level 2 and then standardizing the level-2 scores at level 2. One-way analysis of variance (ANOVA) with random effects model (the unconditional model or Model 0) was used to estimate the proportion of within- and between-class variances in the outcome variables (Raudenbush & Bryk, 2002).

The intraclass correlation coefficient (ICC) measures the proportion of total variance in an outcome variable explained by between-class differences. ICC was 62.0% for math achievement, 7.6% for engagement, 4.1% for interest, 9.4% for effort withdrawal, and 5.8% for avoidance coping.<sup>4</sup> Chi-square tests were performed to examine the significance of between-class variances in the unconditional models. We found that between-class variances were significant for all of the five outcome variables,  $\chi^2$ s (129,  $N = 1926$ ) = 219.61 to 3016.18,  $ps < .001$ .

The next HLM analysis was performed to evaluate the predictive relations of personal goals to student outcomes. A student-level or level-1 model (Model 1) was run to examine the statistical significance of the three level-1 predictors: personal mastery, performance-approach, and performance-avoidance goals. To determine whether the three slopes were fixed or random, we performed a multivariate likelihood-ratio test for each of the outcome variables. The deviance statistic associated with the full random-coefficient regression model, in which all the three slopes were random, was compared with the corresponding statistic associated with the restricted model, in which all the three slopes were fixed. The purpose of the multivariate procedure is to test the omnibus null hypothesis and to protect against the inflation of Type I error rates. If the multivariate likelihood-ratio test was not significant, all the three slopes were fixed. If it was significant, univariate  $\chi^2$  tests would then be performed. The univariate test served as a post hoc procedure to identify which specific slopes were random. If univariate  $\chi^2$  tests were not significant, the slopes of the corresponding level-1 predictors were fixed (Raudenbush & Bryk, 2002). On the basis of the sequential procedures, slopes were either identified to be fixed or random. A fixed slope indicates that level-1 relations are homogeneous across classrooms, whereas a random slope indicates that level-1 relations vary across classrooms. The variation of slopes across classrooms represents a source of variance to be explained by classroom-level variables. Therefore, only random slopes were modeled in further analyses by adding level-2 predictors (see Table 2). In this study, the slopes relating personal mastery goals to avoidance coping, personal performance-approach goals to interest, personal performance-avoidance goals to engagement, personal performance-avoidance

<sup>4</sup> ICC was 8.3% for classroom mastery goal structures and 12.3% for classroom performance goal structures. ICC's for the predictors are reported for descriptive purposes only, because it is not our aim to explain the variance components associated with the predictors.

goals to effort withdrawal, and personal performance-avoidance goals to avoidance coping were found to be random.

Finally, classroom mastery and classroom performance goal structures (the level-2 predictors) were added to build the full model (Model 2). Model 2 was used to test cross-level interactions between classroom goal structures and personal goals as well as their unique main effects:

$$Y_{ij} = \beta_{0j} + \beta_{1j}(\text{PMG}) + \beta_{2j}(\text{PPAP}) + \beta_{3j}(\text{PPAV}) + r_{ij}$$

$$\beta_{0j} = \gamma_{00} + \gamma_{01}(\text{CMG}) + \gamma_{02}(\text{CPG}) + u_{0j}$$

$$\beta_{1j} = \gamma_{10} + \gamma_{11}(\text{CMG}) + \gamma_{12}(\text{CPG}) + u_{1j}$$

$$\beta_{2j} = \gamma_{20} + \gamma_{21}(\text{CMG}) + \gamma_{22}(\text{CPG}) + u_{2j}$$

$$\beta_{3j} = \gamma_{30} + \gamma_{31}(\text{CMG}) + \gamma_{32}(\text{CPG}) + u_{3j}$$

$Y_{ij}$  is the outcome variable, PMG is the personal mastery goal, PPAP is the personal performance-approach goal, PPAV is the personal performance-avoidance goal, CMG is the classroom mastery goal structure, and CPG is the classroom performance goal structure. The equation above represents the most elaborate form of Model 2. If a slope was fixed, the coefficients associated with CMG and CPG would be set to zero (i.e., no level-2 predictors would be added).

The cross-level interaction between classroom goal structures and personal goals can be interpreted as a statistical moderation effect (Baron & Kenny, 1986; Raudenbush & Bryk, 2002). The reinforcing hypothesis is supported if the interaction term is significant and its sign is the same as that of the main effect term for personal goals, the counterbalancing hypothesis is supported if the interaction term is significant and its sign is opposite to that of the main effect term for personal goals, and the additive hypothesis is supported if the interaction term is not significant. As an illustration, in Model 2,  $\gamma_{10}$  is the coefficient for the main effect of personal mastery goals on the outcome variable,  $\gamma_{11}$  is the coefficient for Classroom Mastery Goal Structure  $\times$  Personal Mastery Goal interaction, and  $\gamma_{12}$  is the coefficient for Classroom Performance Goal Structure  $\times$  Personal Mastery Goal interaction. In addition,  $\gamma_{01}$  and  $\gamma_{02}$  can be interpreted as the main effects of classroom mastery and classroom performance goal structures, respectively. A reinforcing effect of classroom mastery goal structures on the relation be-

tween personal mastery goals and the outcome variable is demonstrated if, for example,  $\gamma_{11}$  and  $\gamma_{10}$  are of the same sign, whereas a counterbalancing effect of classroom mastery goal structures is demonstrated if  $\gamma_{11}$  and  $\gamma_{10}$  are of opposite signs. Classroom mastery goal structures do not interact with personal mastery goals if  $\gamma_{11}$  is not significantly different from zero.

We also estimated the percentage of variance explained as a result of adding predictors in successive models. Besides conceptual considerations in relation to our research objectives, the sequence of model building is based on Raudenbush and Bryk's (2002) recommendation on the proper use of variance-explained statistics—"the variance explained in a level-2 parameter, such as  $\beta_{0j}$ , is conditional on a fixed level-1 specification" (p. 150). Thus, the comparison model (or reference model) we used to compute the variance explained statistic is always a nested model of the more complex model that follows (i.e., Model 2 vs. Model 1 or Model 1 vs. Model 0).

### Descriptive Statistics and Zero-Order Correlations

Descriptive statistics and zero-order correlations among the student-level variables used in this study are presented in Table 1. The zero-order correlation between the two level-2 predictors, classroom mastery goal structures and classroom performance goal structures, was not significant ( $r = -.053, p > .05, n = 130$ ).

### Cross-Level Interactions Between Classroom Goal Structures and Personal Goals

Table 2 presents the parameter estimates of fixed effects and results of hypothesis tests for the full model (Model 2). The most notable cross-level interactions were found between classroom performance goal structures and personal performance-avoidance goals. Classroom performance goal structures had significant moderating effects on the relation between personal performance-avoidance goals and engagement ( $\gamma = -.049, p < .05$ ), between performance-avoidance goals and effort withdrawal ( $\gamma = .101, p < .01$ ), and between performance-avoidance goals and avoidance coping ( $\gamma = .090, p < .01$ ).

The moderating effects of classroom performance goal structures on level-1 relations are shown in Figures 1–3. In classrooms with stronger emphasis on performance goals, personal performance-avoidance goals tended to be more negatively related to engagement,

Note. Coefficients significant at the .05 level are boldfaced. Number of level-1 units = 1,926; number of level-2 units = 130.  
<sup>a</sup> Classroom mastery and classroom performance goal structures were not entered as level-2 predictors if the slopes of the corresponding personal goals were fixed.

more positively related to effort withdrawal, and more positively related to avoidance coping. The patterns can be characterized as ordinal interactions, in which nonparallel lines do not cross over within the range of interest (Cohen et al., 2003; Pedhazur, 1997).  
Comparing Model 2 (the full model) with Model 1 (the student-level model), we found that classroom goal structures accounted for 20.2% of the between-class variance in the slope of performance-

avoidance goals predicting engagement, 16.8% in the slope of performance-avoidance goals predicting effort withdrawal, and 25.91% in the slope of performance-avoidance goals predicting avoidance coping.  
No interactions were found between classroom goal structures (either mastery or performance) and personal mastery goals and between classroom goal structures and personal performance-

Figure 1. Interaction between classroom performance goal structure and personal performance-avoidance goal predicting engagement.

Figure 2. Interaction between classroom performance goal structure and personal performance-avoidance goal predicting effort withdrawal.

approach goals. For variables that produced interactions, the interaction pattern was of the ordinal type, suggesting that the main effects can be used to summarize the overall predictor-outcome relations. Therefore, we proceed to present results on the main effects of personal goals and classroom goal structures whether or not interactions were found.

#### Main Effects of Personal Goals

As shown in Table 2, personal mastery goals were positively related to math achievement ( $\gamma = .140, p < .001$ ), engagement ( $\gamma = .401, p < .001$ ), and interest ( $\gamma = .764, p < .001$ ). Moreover, personal mastery goals were negatively related to effort with-

Figure 3. Interaction between classroom performance goal structure and personal performance-avoidance goal predicting avoidance coping.

drawal ( $\gamma = -.259, p < .001$ ) and avoidance coping ( $\gamma = -.300, p < .001$ ).

Personal performance-approach goals were positively related to engagement ( $\gamma = .085, p < .001$ ). For other outcomes, personal performance-approach goals were not significant predictors at the .05 level.

Personal performance-avoidance goals were negatively related to math achievement ( $\gamma = -.094, p < .001$ ) and engagement ( $\gamma = -.102, p < .001$ ), but unrelated to interest ( $\gamma = -.021, p > .05$ ). Moreover, personal performance-avoidance goals were positively related to effort withdrawal ( $\gamma = .386, p < .001$ ) and avoidance coping ( $\gamma = .237, p < .001$ ).

Comparing Model 1 (the student-level model) with Model 0 (the unconditional model), we found that personal goals accounted for 5.9% of the within-class (or level-1) variance for math achievement, 19.1% for engagement, 59.4% for interest, 25.7% for effort withdrawal, and 16.6% for avoidance coping.

### *Main Effects of Classroom Goal Structures*

As shown in Table 2, classroom mastery goal structures were positively related to math achievement ( $\gamma = .129, p < .05$ ), but negatively related to effort withdrawal ( $\gamma = -.066, p < .05$ ) and avoidance coping ( $\gamma = -.097, p < .001$ ). In contrast, classroom performance goal structures were negatively related to math achievement ( $\gamma = -.385, p < .01$ ) and engagement ( $\gamma = -.077, p < .01$ ) but positively related to effort withdrawal ( $\gamma = .126, p < .001$ ) and avoidance coping ( $\gamma = .099, p < .001$ ).

Comparing Model 2 (the full model) with Model 1 (the student-level model), we found that classroom goal structures accounted for 27.2% of the between-class (or level-2) variance for math achievement, 14.6% for engagement, 10.5% for interest, 40.3% for effort withdrawal, and 56.8% for avoidance coping, after controlling for personal goals at level 1.

## Discussion

The main purposes of this study were to examine how classroom goal structures moderated the predictive relations between personal goals and student outcomes, as well as how these variables operated additively at the individual and classroom levels. Specifically, we used HLM to test three hypotheses: the reinforcing hypothesis, the counterbalancing hypothesis, and the additive hypothesis.

### *Cross-Level Interactions Between Classroom Goal Structures and Personal Goals*

The reinforcing hypothesis has received empirical support from the findings of cross-level interactions between classroom performance goal structures and personal performance-avoidance goals in predicting engagement, effort withdrawal, and avoidance coping. We found that a strong focus on classroom performance goal structures tended to reinforce (or exacerbate) the negative association between personal performance-avoidance goals and student engagement. The reinforcing effects are also evident in predicting maladaptive motivational outcomes. High levels of classroom performance goal structures tended to reinforce (or exacerbate) the positive predictive relations of personal performance-avoidance

goals to both effort withdrawal and avoidance coping. In other words, our finding suggests that in classrooms that emphasize demonstrating ability, social comparison of performance, and competition for good grades, students who are oriented toward performance-avoidance goals would be less likely to be engaged in their math classes, more likely to withdraw their effort in learning math, and more likely to give up when the work is difficult or boring.

The additive hypothesis was supported by the finding that classroom performance goal structures did not moderate the predictive relations of either personal mastery goals or performance-approach goals to any of the outcome variables. It was also supported by the finding that classroom mastery goal structures did not interact with any of the three personal goals in predicting any of the outcome variables, which indicated that classroom mastery goal structures operated in an additive way with personal goals to predict achievement and motivational outcomes.

Our findings are by and large consistent with Linnenbrink's (2005), despite differences between the two studies in numerous methodological and sample characteristics. In her quasi-experimental study, she found that classroom goal conditions did not interact with either personal mastery goals or personal performance-approach goals. Linnenbrink, however, did not include personal-avoidance goals in her study, which turn out to be critical for testing the interaction hypotheses in this study.

This study extends previous research in two ways. First, our findings triangulate Linnenbrink's (2005) findings with respect to personal mastery and personal performance-approach goals by using an alternative research design and analytic approach. This approach allows us to associate specific HLM results with specific hypotheses in a systematic way. Second, including personal performance-avoidance goals in testing the interaction hypotheses provides a richer and more complete picture of person-context interactions by demonstrating the moderating effects of classroom performance goal structures on the maladaptive relations between personal performance-avoidance goals and motivational outcomes.

Overall, we obtained corroborative evidence for the additive and reinforcing hypotheses, but no evidence for the counterbalancing hypothesis. Whether and how classroom goal structures interact with personal goals depend on the specific combination of classroom goal structures and personal goals and the specific outcome variables used in the analysis. Before we elaborate on the implications of our findings for educational practices, we first discuss and interpret the main effect findings because it is important to take into account multiple levels of analysis in making recommendations for educational practices.

### *Main Effects of Personal Goals*

We found that personal mastery goals were positively related to math achievement, engagement, and interest in math, but negatively related to effort withdrawal and avoidance coping. The patterns for performance-avoidance goals were quite consistent, but in the opposite direction—performance-avoidance goals were negatively related to math achievement and engagement, but positively related to effort withdrawal and avoidance coping. Performance-approach goals were positively related to engagement, but unrelated to the other outcome variables. Overall, the main effects of personal goals are consistent with the following

general conclusions derived from prior research: (a) personal mastery goals are adaptive, (b) performance-avoidance goals are maladaptive; and (c) evidence for the relations between performance-approach goals and outcomes is mixed and inconclusive (Elliot, 2005; Harackiewicz et al., 2002; Midgley et al., 2001). The demonstration of consistent results based on an Asian sample enhances the cross-cultural generalizability of the achievement goal theory.

### *Main Effects of Classroom Goal Structures*

Classroom mastery goal structures were positive predictors of math achievement and negative predictors of effort withdrawal and avoidance coping. In other words, in classrooms where teachers were perceived to emphasize learning and improving, students tended to perform better in math tests, were less likely to withdraw effort in their math work, and were less likely to give up when the work was difficult or boring. In contrast, classroom performance goal structures were negative predictors of math achievement and engagement, but positive predictors of effort withdrawal and avoidance coping. That is, in classrooms with stronger emphasis on demonstrating one's competence, social comparison of ability, and competition for high grades, students tended to perform worse in math tests, were less likely to pay attention and participate in group work in class, were more likely to withdraw effort in their math work, and were more likely to give up when the work was difficult or boring.

Prior research that adopted a multilevel framework and used HLM procedures has documented similar patterns of results,<sup>5</sup> especially for maladaptive outcomes. For example, classroom mastery goal structures were found to be significant negative predictors of self-handicapping (Turner et al., 2002), avoidance of help-seeking (Karabenick, 2004; A. M. Ryan et al., 1998; Turner et al., 2002), and disruptive behaviors (Kaplan, Gheen, et al., 2002). In contrast, classroom performance goal structures were positively related to self-handicapping (Urdan, Midgley, & Anderman, 1998), avoidance of help-seeking (Karabenick, 2004; A. M. Ryan et al., 1998), and disruptive behavior (Kaplan, Gheen, et al., 2002). This study provides corroborative evidence for the role of classroom mastery goal structures and classroom performance goal structures in students' achievement and motivational outcomes in an Asian context. In addition, by including both adaptive and maladaptive outcomes in the same study, we provide a comprehensive set of findings to document differential relations for different types of classroom goal structure.

Comparisons of level-1 and level-2 relations reveal that personal mastery goals and classroom mastery goal structures had similar patterns of predictive relations to outcomes. Surprisingly, classroom performance goal structures, despite the focus on the approach dimension, were consistent with personal performance-avoidance goals (but not with personal performance-approach goals) in predicting outcomes at their respective levels of analysis. These findings have important implications for practice, which we elaborate in the next section.

### *Implications for Classroom Practices*

Our study underscores the importance of studying achievement motivation in a multilevel framework. This point is particularly pertinent in light of recent debates about whether personal perfor-

mance-approach goals are adaptive or not (Harackiewicz et al., 2002; Kaplan & Middleton, 2002; Midgley et al., 2001). In the current study, personal performance-approach goals were positively related to engagement and were unrelated to other outcome variables. From the individual level of analysis, it seems harmless or even beneficial to emphasize the approach dimension of performance goals. However, this finding alone cannot be directly translated into recommendations for educational practices because interventions that involve changing teachers' classroom practices are usually conducted at the classroom level. Classroom goal structures could have additive effects on student outcomes independent of their personal goals, as well as moderating effects on the relations between personal goals and student outcomes. We therefore caution against making recommendations for classroom practices on the basis of research conducted solely at the individual level of analysis (Roeser, 2004).

In line with the above argument, we take into account multilevel relations in drawing our conclusions. Both the interaction and main effect findings regarding the maladaptive role of classroom performance goal structures suggest that teachers should deemphasize performance goals in their classrooms, even if teachers' goal messages are meant to encourage students to demonstrate superior ability and to get higher grades than their peers. As our findings indicate, classroom performance goal structures are negatively related to math achievement and engagement, and positively related to effort withdrawal and avoidance coping. What is worrisome is that classroom performance goal structures appear to be especially detrimental to students who strongly endorse performance-avoidance goals, due to the reinforcing or exacerbating effects on the maladaptive relations between performance-avoidance goals and outcomes. Given the robust and consistent empirical generalization of the negative impact of personal performance-avoidance goals on student outcomes (see Elliot, 2005; Pintrich & Schunk, 2002; Urdan, Ryan, Anderman, & Gheen, 2002, for reviews), students who are oriented toward performance-avoidance goals are especially at-risk for maladaptive outcomes. Emphasizing performance goals in the classroom may further exacerbate the risk to this group of students, even if teachers focus on the approach dimension of classroom performance goal structures.

In addition, given the convergence of evidence from the current study and prior research (Kaplan, Gheen, et al., 2002; Karabenick, 2004; A. M. Ryan et al., 1998; Turner et al., 2002) regarding the adaptive role of both classroom mastery goal structures and personal mastery goals, it is advisable for teachers to place greater emphasis on mastery goals in their classrooms. Our findings show that classroom mastery goal structures and personal mastery goals operate in an additive way and the patterns of predictor-outcome relations are similar at both the classroom-level and student-level of analysis.

<sup>5</sup> A number of prior studies investigated the relations between classroom goal structures and outcomes at a single level (student-level) of analysis (e.g., Anderman & Midgley, 1997; Church et al., 2001; Kaplan & Maehr, 1999; Roeser et al., 1996). Because the within-class and between-class components of students' perceptions of classroom goal structures were not separated in these studies, it is difficult to compare their results with ours.

## Limitations

Several limitations of this study should be noted. First, the use of correlational data does not permit us to infer causal flows from classroom goal structures and personal goals to student outcomes. Nevertheless, the evidence that supports the additive hypothesis (i.e., classroom mastery goal structures and classroom performance goal structures did not interact with either personal mastery goals or personal performance-approach goals) shows remarkable consistency with prior research using a quasi-experimental design (Linnenbrink, 2005). We believe that our findings and Linnenbrink's are complementary and mutually corroborative. Moreover, we extend previous research by demonstrating cross-level interactions between classroom performance goal structures and personal performance-avoidance goals. This finding, however, needs to be triangulated by quasi-experimental or experimental studies. It is hoped that our study will stimulate further research that uses alternative research designs to fully understand the complex interplay between personal goals and classroom goal structures.

Second, our measure of classroom performance goal structures primarily assessed the approach dimension. But it is important to note that, surprisingly, our "approach measure" had significant interactions with personal performance-avoidance goals, but not with personal performance-approach goals. Moreover, classroom performance goal structures were consistent with personal performance-avoidance goals (but not with personal performance-approach goals) in predicting outcomes at their respective levels of analysis. Thus, the fact that we focused on the approach dimension of classroom performance goal structures actually strengthens the case against emphasizing performance goals in the classroom. Students who strongly endorse performance-avoidance goals may not necessarily interpret the "approach" aspect of the performance goal messages despite the intentions of their teachers. It remains an empirical question whether students can distinguish between the approach and avoidance dimensions of classroom goal structures and, if they do, how they would interpret the goal messages conveyed to them. Karabenick (2004) reported a zero-order correlation of .91 between aggregated student perceptions of classroom performance-approach goals and classroom performance-avoidance goals, whereas Kaplan, Gheen, et al. (2002) reported the corresponding correlation to be .41. A comprehensive and systematic validity study would be needed to determine the empirical viability and utility of distinguishing between the approach and avoidance dimensions of classroom performance goal structures.

Third, our measures of classroom goal structures were based on students' self-reports, which were their subjective interpretations of goal messages conveyed by their teachers. There are disagreements in the literature about the merits of using student perceptions and interpretations of goal messages (or the functional significance of the goal context) are more important than the objective reality of classroom contexts in influencing students' achievement-related behaviors (Ames, 1992; Meece et al., 2006; A. M. Ryan et al., 1998; R. M. Ryan & Grolnick, 1986). When both teachers' reports and students' reports of classroom goal structures were used in the same study, aggregated student-report measures tended to be more strongly related to outcomes than did teacher-report measures (Kaplan, Gheen, et al., 2002; A. M. Ryan et al., 1998; Urdan et al., 1998). Moreover, there is evidence

showing that students' self-reports of classroom goal structures were systematically related to teachers' practices based on classroom observations (Patrick, Anderman, Ryan, Edelin, & Midgley, 2001). Furthermore, from a measurement perspective, aggregation of student perceptions reduces measurement and other unsystematic errors and hence produces more reliable measures than teachers' reports or classroom observations based on a single observer.

However, a limitation of student perceptions is that it is difficult to make recommendations for classroom practices without understanding how objective classroom environments impact student outcomes (Linnenbrink, 2005; Urdan, 1997, 2004). Experimental and quasi-experimental studies of how manipulations of objective goal-related features in the classroom may alter students' personal goals and achievement-related outcomes would provide practitioners with concrete guidelines and specific practices for altering classroom goal structures. In addition, there is a need for more research that uses multiple methods such as classroom observations, interviews, simulated recalls, and experimental manipulations to triangulate and validate findings based on student perceptions (Urdan, 2004).

A fourth issue in relation to achievement goal research is the stability of personal goals. Experimental manipulations have been found to be effective in eliciting or changing particular personal goals in the laboratory setting, at least briefly, suggesting that personal goals could be responsive to situational demands and cues (Barron & Harackiewicz, 2001; Elliot & Harackiewicz, 1996; Elliott & Dweck, 1988). But evidence based on longitudinal survey research has shown that personal goals are relatively stable over time (Anderman & Midgley, 1997; Midgley et al., 1998; Wolters, Yu, & Pintrich, 1996). The mixed evidence base has led some authors to conclude that personal goals could display both dispositional and situational characteristics, depending on the research context (Elliot, 2005; Urdan, 1997, 2004). In experimental settings, goal messages are usually unambiguous and situational demands are strong, whereas in natural classroom environments, goal messages are usually mixed and the situational demands are weaker than those in experimental settings (Urdan, 1997). Although we expected personal goals to be relatively stable as this study was conducted in natural classroom settings, it is possible that classroom goal structures would have had time to influence personal goals as the data were collected in the 8th month from the beginning of the school year.

A limitation of this study is that a cross-sectional design does not allow us to empirically assess the stability of personal goals over time. This design could only capture the product of a series of potentially complex processes at a particular point in time, but the specific processes involved remain unclear. For example, although the current study demonstrates that, at the time of data collection, the relation between personal performance-avoidance goals and avoidance coping tended to be stronger in classrooms with higher levels of performance goal structures (a reinforcing-exacerbating pattern), the specific processes leading to this pattern of person-context interaction remain unclear. If classroom goal structures influenced personal goals, which in turn influenced achievement-related outcomes, the product of such mediating processes, together with those of any other processes, would be registered as the final product (statistical relations) at the point of data collection. Evidence on the stability (or instability) of personal goals would allow researchers to assess the plausibility of the mediation expla-

nation.<sup>6</sup> Future research that employs a longitudinal design to track students' personal goals over time would help to shed light on the processes involved (Anderman et al., 1999; Anderman & Midgley, 1997).

<sup>6</sup> It is important to note that mediation and moderation are not mutually exclusive phenomena. The validity of our statistical findings (e.g., the statistical moderating effects of classroom performance goal structures on the relations between personal performance-avoidance goals and student outcomes) does not rely on the assumption of the absence of mediation by personal goals. As explained by Muller, Judd, & Yzerbyt (2005), "the mediation question focuses on the intervening mechanism that produces the treatment effect. The moderation question focuses on factors that affect the magnitude of the treatment effect. It is important to note that these two processes may be combined in informative ways, such that moderation is mediated or mediation is moderated" (p. 852).

## Appendix

## Sample Items for Self-Report Scales

*Classroom Mastery Goal Structure (4 items)*

My math teacher wants us to really understand the subject, not just to remember facts or rules.

*Classroom Performance Goal Structure (5 items)*

My math teacher thinks that it is more important to do well in math tests than to learn new things.

*Personal Mastery Goal (5 items)*

An important reason I do my math work is that I like to learn new things.

*Personal Performance-Approach Goal (4 items)*

I like to show my teacher that I am smarter than the other pupils in my math class.

*Personal Performance-Avoidance Goal (4 items)*

I do my math work because I do not want the teacher to think that I am stupid.

*Interest (4 items)*

I enjoy doing math.

*Engagement (5 items)*

I pay attention well in my math class.  
I try my best to contribute during small group discussions.

*Effort Withdrawal (4 items)*

I do not work hard on my math homework.

*Avoidance Coping (3 items)*

When the work in math is difficult, I give up.

# Problem Solving and Computational Skill: Are They Shared or Distinct Aspects of Mathematical Cognition?

Lynn S. Fuchs and Douglas Fuchs  
Vanderbilt University

Karla Stuebing and Jack M. Fletcher  
University of Houston

Carol L. Hamlett and Warren Lambert  
Vanderbilt University

The purpose of this study was to explore patterns of difficulty in 2 domains of mathematical cognition: computation and problem solving. Third graders ( $n = 924$ ; 47.3% male) were representatively sampled from 89 classrooms; assessed on computation and problem solving; classified as having difficulty with computation, problem solving, both domains, or neither domain; and measured on 9 cognitive dimensions. Difficulty occurred across domains with the same prevalence as difficulty with a single domain; specific difficulty was distributed similarly across domains. Multivariate profile analysis on cognitive dimensions and chi-square tests on demographics showed that specific computational difficulty was associated with strength in language and weaknesses in attentive behavior and processing speed; problem-solving difficulty was associated with deficient language as well as race and poverty. Implications for understanding mathematics competence and for the identification and treatment of mathematics difficulties are discussed.

**Keywords:** calculations, word problems, cognitive predictors, mathematics

Mathematics, which involves the study of quantities as expressed in numbers or symbols, comprises a variety of related branches. In elementary school, for example, mathematics is conceptualized in strands such as concepts, numeration, measurement, arithmetic, algorithmic computation, and problem solving. In high school, curriculum offerings include algebra, geometry, trigonometry, and calculus. Little is understood, however, about how different aspects of mathematical cognition relate to one another (i.e., which aspects of performance are shared or distinct, or how difficulty in one domain corresponds with difficulty in another). Such understanding would provide theoretical insight into the nature of mathematics competence and practical guidance about the identification and treatment of mathematics difficulties.

The purpose of the present study was to explore the overlap of difficulty with two aspects of primary-grade mathematical cognition and to examine how characteristics differ among subgroups with difficulty in one, the other, both, or neither. The first aspect of performance was computation, including skill with number

combinations (e.g.,  $2 + 5$ ;  $8 - 3$ ) and procedural computation (e.g.,  $25 + 38$ ;  $74 - 22$ ). The second aspect of performance was problem solving, including one-step, contextually straightforward word problems (e.g., John had 9 pennies. He spent 3 pennies at the store. How many pennies did he have left?) and multistep, contextually more complex problems (e.g., Fred went to the ballgame with 2 friends. He left his house with \$42. While at the game, he bought 5 hotdogs and 3 sodas. The hot dogs cost \$10 each, and the sodas cost \$5 each. How much did Fred spend?).

The major distinction between computation and problem solving is the addition of linguistic information that requires children to construct a problem model. Whereas a computation problem is already set up for solution, a word problem requires students to use the text to identify missing information, construct the number sentence, and derive the calculation problem for finding the missing information. This transparent difference would seem to alter the nature of the task, but no studies have examined how difficulty in one subdomain corresponds to difficulty in the other and whether students' cognitive characteristics differ as a function of where the mathematics difficulty resides.

By contrast, a related literature does focus on the interplay between math and reading. In these studies, math difficulty typically is defined on a broad measure tapping multiple aspects of performance, then subgroups are formed to determine how performance on mathematics domains differs with or without concurrent reading difficulty. Research has shown that students with difficulty in both math and reading (usually defined in terms of word recognition) experience more pervasive deficits in computation (e.g., Jordan & Hanich, 2000) and problem solving (e.g., Fuchs & Fuchs, 2002; Hanich, Jordan, Kaplan, & Dick, 2001; Jordan & Hanich, 2000). This may occur due to a different pattern of

underlying deficits in domain-general abilities associated with comorbidity. Other work (e.g., Jordan, Hanich, & Kaplan, 2003; Landerl, Began, & Butterworth, 2004), however, has shown that students with general math difficulty, with and without reading problems, experience comparable deficits on number combinations. An older body of research suggested that specific math difficulty, usually defined as performance on a broad computational task, is associated with difficulties in nonverbal processing (spatial cognition, working memory) and procedural knowledge (Geary, 1993; Rourke & Finlayson, 1978); concurrent reading and math difficulties reflect more pervasive language and working-memory problems.

This line of work, which speaks to the issue of reading difficulty, is important for generating hypotheses about the nature of mathematics disability as well as its identification and treatment. This literature does not, however, address the issue of whether difficulty within mathematics domains is better conceptualized as shared or distinct. Four large-scale studies speak indirectly to this issue by examining the cognitive characteristics associated with computational and problem-solving skill among representative samples. Studying 353 first through third graders, Swanson and Beebe-Frankenberger (2004) identified working memory as an ability that contributed to strong performance across both areas of mathematical cognition, but some unique cognitive abilities also emerged as important: phonological processing for computation and fluid intelligence as well as short-term memory for simple word problems. In an extension of this work following students' development of calculations and problem-solving skill over 1 year, Swanson (2006) identified predictors of computation (inhibition or controlled attention, vocabulary knowledge, visual-spatial working memory) that differed from problem solving (working-memory's executive system, operationalized as listening span, backward digit span, and digit/sentence span). A latent variable of reading (i.e., phonological processing, timed and untimed reading of real words, timed reading of pseudowords, and comprehension) accounted for skill in both math outcomes.

With a sample of 312 third graders, Fuchs et al. (2006) examined the concurrent cognitive correlates of computation versus simple word problems, this time controlling for the role of arithmetic skill within simple word problems. Teacher ratings of inattentive behavior were identified as a correlate common to both subdomains of math, but the remaining abilities differed: for computation, phonological decoding and processing speed; for word problems, nonverbal problem solving, concept formation, sight word efficiency, and language. The fourth study (Fuchs et al., 2005) used beginning-of-the-year cognitive abilities to predict the development of skill across the year among 272 first graders. Results again suggested some common and some unique patterns of cognitive abilities. The common predictors were working memory and ratings of attention. The unique predictors were phonological processing for computation and nonverbal problem solving for simple word problems.

Across these studies, some findings recur; others are idiosyncratic. But together, the results indicate that some abilities underlying these domains of mathematical cognition are unique. This provides the basis for hypothesizing that the cognitive dimensions underlying difficulty in each of these domains may also be distinct and that difficulty in these two domains may be distinct. This has implications for understanding, identifying, and treating mathe-

matics difficulties. In a related way, such knowledge would help determine whether the distinction in these domains newly introduced into the 2004 reauthorization of the Individuals with Disabilities Education Act is viable. That is, although the reauthorized law, which guides the identification and treatment of students with disabilities throughout schools in the United States, makes a distinction between problem-solving and computational forms of mathematics disability, little prior work is available to assess the validity of this distinction.

In the present study, we extended the literature by addressing these issues directly. We began by conducting preliminary analyses to evaluate the predictors of each math outcome using assessments of math skills and cognitive domains in a large population-based sample of children in third grade. In line with the four earlier studies on representative samples, we hypothesized that different cognitive skills would be associated with each domain, even when we accounted for shared variance in computation and problem solving. Our major analyses, however, focused specifically on determining whether children with extreme deficits in computation or problem solving represent distinct groups. We identified students at the lower end of the distribution on computation, on problem solving, on both, or on neither, and we examined the extent to which students actually experienced difficulty in one domain but not the other. Then, we assessed how the demographic and cognitive profiles associated with these subgroups differed. Using profile analysis, we hypothesized that groups based on computation or problem solving would show different profiles and that the presence of both difficulties would show features of both domains, reflecting a comorbid association. We contrasted profile analysis findings based on a univariate versus a multivariate approach.

We note that the vast majority of prior work examining the cognitive correlates of primary-grade mathematics performance focused on a limited set of cognitive abilities related to a single aspect of math skill, rather than studying how these abilities operate within a multivariate framework to explain different aspects of mathematical cognition. For this reason, the literature provides the basis for deliberate hypotheses about which cognitive abilities may mediate which aspect of third-grade math performance. The literature does not, however, provide the basis for specifying an integrated theory about how these variables operate in coordinated fashion to explain computation versus problem solving. Before describing the method of the present study, we summarize the basis for our hypotheses about which cognitive dimensions might be related to which aspect of mathematical cognition.

In terms of computation, prior work provides the basis for hypothesizing that attentive behavior, working memory, and processing speed may help determine skill. Because computation requires a series of steps, attentive behavior (i.e., low distractibility) may enhance performance. Russell and Ginsburg (1984) provided suggestive evidence on this possibility when they compared math-disabled fourth graders to normal fourth graders and normal third graders. Results indicated that the algorithmic errors of math-disabled students were similar to those of both normal groups, but math-disabled students more closely resembled younger normal counterparts in detecting those errors. More recently, Swanson (2006) showed that inhibitory control predicted the development of computation but not problem-solving skill.

Second, prior work has implicated *working memory* (e.g., Geary, Brown, & Samaranayake, 1991; Hitch & McAuley, 1991; Siegel & Linder, 1984; Webster, 1979; Wilson & Swanson, 2001), or the capacity to maintain target memory items while processing an additional task (Daneman & Carpenter, 1980). Although the relation between working memory and memory-based retrieval of computation has been repeatedly documented, the nature of that relation is unclear. As described by Geary (1993), working memory involves component skills including, but not limited to, rate of decay (creating difficulties in holding the association between a problem stem and its answer) and attentive behavior (hence the finding that math-disabled children monitor problem solving less well than non-math-disabled children; Butterfield & Ferretti, 1987; Geary, Widaman, Little, & Cormier, 1987). In addition, memory span appears to be related to how quickly numbers can be counted (Geary, 1993).

It is not surprising, therefore, that *processing speed*, or the efficiency with which simple cognitive tasks are executed (R. Case, 1985), represents a promising candidate. Processing speed may dictate how quickly numbers can be counted. With slower processing, the interval for deriving counted answers and for pairing a problem stem with its answer in working memory increases; this creates the possibility that decay sets in before completing the computational sequence. Bull and Johnston (1997) found that processing speed was the best predictor of computational competence among 7-year-olds, subsuming all of the variance accounted for by long- and short-term memory, even with reading performance controlled. More recently, Hecht, Torgesen, Wagner, and Rashotte (2001) provided corroborating data on the importance of processing speed as a correlate of computational skill while controlling for vocabulary knowledge.

As for problem solving, prior work examining which cognitive processes mediate arithmetic word problems has focused heavily on working memory, probably because research (e.g., Hitch & McAuley, 1991; Siegel & Ryan, 1989) shows that children with learning disabilities experience concurrent difficulty with working memory (e.g., Siegel & Ryan, 1989; Swanson, Ashbaker, & Sachse-Lee, 1996) and mathematical problem solving (e.g., L. P. Case, Harris, & Graham, 1992; Swanson, 1993). Also, theoretical frameworks (e.g., Kintsch & Greeno, 1985; Mayer, 1992) posit that word problems involve construction of a problem model, which appears to require working-memory capacity. For example, according to Kintsch and Greeno, when people solve word problems, new sets are formed on-line as the story is processed. When a proposition that triggers a set-building strategy is completed, the appropriate set is formed and the relevant propositions are assigned places in the schema. As new sets are formed, previous sets that had been active in the memory buffer are displaced.

In line with theoretical models implicating working memory, the literature provides support for its importance. For example, Passolunghi and Siegel (2001) found that 9-year-olds, characterized as good or poor problem solvers, differed on working-memory tasks. Other researchers have found corroborating evidence using similar methods (e.g., LeBlanc & Weber-Russell, 1996; Passolunghi & Siegel, 2004; Swanson & Sachse-Lee, 2001). At the same time, other studies have raised questions about the robustness of the relation. For example, among typically developing third and fourth graders, Swanson, Cooney, and Brock (1993) found only a weak relation between working memory and problem solution accuracy,

and this relation disappeared once reading comprehension was considered. The other leading candidates are attentive behavior, nonverbal problem solving, language ability, reading skill, and concept formation.

In studies involving attention, most work has focused on the inhibition of irrelevant stimuli, with mixed results. Passolunghi and colleagues ran a series of studies suggesting the importance of inhibition. For example, comparing good and poor problem solvers, Passolunghi, Cornoldi, and De Liberto (1999) found comparable storage capacity with inefficiencies of inhibition (i.e., poor problem solvers remembered less relevant but more irrelevant information in math problems). In contrast, Swanson and Beebe-Frankenberger (2004) and Swanson (2006) found no evidence that inhibition contributed to problem-solving skill. Research has, however, rarely studied the role of attention more broadly. An exception is Fuchs et al. (2005), who found that a teacher rating scale of attentive behavior predicted the development of first-grade skill with word problems.

*Nonverbal problem solving*, or the ability to complete patterns presented visually, has been identified as a unique predictor in the development of problem-solving skill across first grade (Fuchs et al., 2005), a finding corroborated by Agness and McLone (1987). This is not surprising, because word problems, in which the problem narrative poses a question entailing relationships between numbers, appear to require conceptual representations. Language ability is also important to consider given the obvious need to process linguistic information when building a problem representation of an arithmetic word problem. In fact, Jordan, Levine, and Huttenlocher (1995) documented the importance of language ability when they showed that kindergarten and first-grade language-impaired children (receptive vocabulary and grammatic closure < 30th percentile) performed significantly lower than nonimpaired peers on arithmetic word problems. Finally, it is hard to ignore the possibility that reading skill may underlie skill in problem solving. Reading is transparently involved, even when problems are read aloud to children, because reading skill provides continuing access to the written problem narrative after the adult reading has been completed. This potentially reduces the load on working memory and thereby facilitates solution accuracy. Swanson (2006) recently identified reading as a predictor of computational as well as problem-solving skill.

## Method

### Participants

The data described in this paper were collected as part of a prospective 4-year study assessing the effects of mathematical problem-solving instruction and examining the developmental course and cognitive predictors of mathematical problem solving. The data in the present article were collected with the first-, second-, and third-year cohorts at the first assessment wave, sampling from 1,958 students in 89 third-grade classrooms in 10 Title 1 schools and 3 non-Title 1 schools in a southeastern metropolitan school district.

The sampling process was designed to yield a representative sample. That is, from these 1,958 students, we randomly sampled 990 students for participation, blocking within classroom and within three strata: (a) 25% of students with scores 1 *SD* below the

mean of the entire distribution on the Test of Computational Fluency (see *Math Measures*); (b) 50% of students with scores within 1 *SD* of the mean of the entire distribution on the Test of Computational Fluency; and (c) 25% of students with scores 1 *SD* above the mean of the entire distribution on the Test of Computational Fluency. Of these 990 students, we had complete data for the variables reported in the present study on 924 children, who were the basis for the present report. As measured on the two-subtest Wechsler Abbreviated Scale of Intelligence (WASI; Wechsler, 1999), IQ averaged 97.68 (*SD* = 14.26). Normal curve equivalent scores on the TerraNova (CTB/McGraw-Hill, 1997), administered the previous spring by the school district, averaged 55.40 (*SD* = 16.72) for the reading composite and 55.75 (*SD* = 20.15) for the mathematics composite. Standard scores on the Woodcock-Johnson III Tests of Achievement (WJ-III; Woodcock, McGrew, & Mather, 2001) Applied Problems averaged 102.25 (*SD* = 13.51), and standard scores on the Woodcock Reading Mastery Tests—Revised Word Identification (Woodcock, 1998) averaged 101.05 (*SD* = 10.05). Of the 924 students, 437 (47.3%) were male, and 499 (54.0%) received subsidized lunch. Ethnicity was distributed as follows: 395 (42.5%) African American, 363 (39.3%) European American, 94 (10.2%) Hispanic, 17 (1.8%) Kurdish, and 55 (6.0%) other. Schools had identified 73 students (7.9%) as having a disability (i.e., learning disability, speech impairment, language impairment, attention-deficit/hyperactivity disorder, health impairment, or emotional behavioral disorder).

### Procedure

In this report, we describe only the subset of measures on which we report data. The math measures were administered in large-group arrangement in September of third grade during three sessions each lasting 30 to 60 min. These large-group sessions included three tests of computational skill (Addition Fact Fluency, Subtraction Fact Fluency, and Test of Computational Fluency) and three tests of word problem skill (Simple Word Problems, Algorithmic Word Problems, and Complex Word Problems). Measures of eight (of the nine) cognitive dimensions were administered individually in September and October of third grade during two 45-min sessions: Woodcock Diagnostic Reading Battery Listening Comprehension, Test of Language Development—Primary Grammatical Closure, WASI Vocabulary, WJ-III Retrieval Fluency, WJ-III Concept Formation, WASI Matrix Reasoning, Working Memory Test Battery for Children Listening Recall, WJ-III Numbers Reversed, Woodcock Reading Mastery Tests—Revised Word Identification, and WJ-III Visual Matching. Tests were administered by trained examiners, each of whom had demonstrated 100% accuracy during mock administrations. All individual sessions were audiotaped, and 19.7% of tapes, distributed equally across testers, were selected randomly for accuracy checks by an independent scorer. Agreement was between 98.7% and 99.9%. In October, classroom teachers completed the Strengths and Weaknesses of Attention-Deficit/Hyperactivity Disorder-Symptoms and Normal-Behavior (SWAN) Rating Scale, the ninth cognitive dimension, on each student.

### Math Measures

*Addition and subtraction fact fluency.* The Grade 3 Math Battery (Fuchs, Hamlett, & Powell, 2003) incorporates two math

fact retrieval subtests. Addition Fact Fluency comprises 25 addition fact problems with answers from 0 to 12 and with addends from 0 to 9. Problems are presented horizontally on one page. Students have 1 min to write answers. The score is the number of correct answers. Agreement, calculated on 20% of protocols by two independent scorers, was 99.8%. For the representative sample, coefficient alpha was .91; criterion validity with the previous spring's TerraNova (CTB/McGraw-Hill, 1997) Total Math score was .53 for the 844 students for whom we had TerraNova scores. Subtraction Fact Fluency comprises 25 subtraction fact problems with answers from 0 to 12 and with minuends/subtrahends from 0 to 18. Problems are presented horizontally on one page. Students have 1 min to write answers. The score is the number of correct answers. Agreement, calculated on 20% of protocols by two independent scorers, was 98.5%. For the representative sample, coefficient alpha was .92, and criterion validity with the previous spring's TerraNova Total Math score was .51 for the 844 students for whom we had TerraNova scores.

*Procedural computation.* The Test of Computational Fluency (Fuchs, Hamlett, & Fuchs, 1990) is a one-page test displaying 25 items that sample the typical second-grade computation curriculum, including adding and subtracting number combinations and algorithmic computation. Students have 3 min to complete as many answers as possible. The score is the number of correct responses. Staff entered responses into a computerized scoring program on an item-by-item basis, with 15% of tests reentered by an independent scorer. Data-entry agreement was 99.6%. For the representative sample, coefficient alpha was .94, and criterion validity with the previous spring's TerraNova (CTB/McGraw-Hill, 1997) Total Math score was .60 for the 844 students for whom we had TerraNova scores.

*Simple arithmetic word problems.* Following Jordan and Hanich (2000; adapted from Carpenter & Moser, 1984; Riley & Greeno, 1988; Riley, Greeno, & Heller, 1983), Story Problems comprises 14 one-step word problems that express change, combine, compare, and equalize relationships among numbers and require sums or subtrahends of 9 or less for solution. The tester reads each item aloud while students follow along on their own copies of the problems. Students have 30 s to respond to each item before the tester moves to the next one, and students can ask for rereading(s) as needed. The score is the number of correct answers. A second scorer independently rescored 20% of protocols, with agreement of 99.9%. For the representative sample, coefficient alpha was .86, and criterion validity with the previous spring's TerraNova (CTB/McGraw-Hill, 1997) Total Math score was .62 for the 844 students for whom we had TerraNova scores.

*Algorithmic word problems.* Algorithmic Word Problems (Fuchs et al., 2003) comprises 10 word problems, each of which requires one to four steps. The measure samples four problem types, asking students to (a) apply step-up functions, (b) add multiple quantities of items each with different prices, (c) find half, or (d) sum a quantity derived from a pictograph with another addend. The tester reads each item aloud while students follow along on their own copies of the problems. The tester progresses to the next problem when all but one or two students have their pencils down, indicating they are finished. Students can ask for rereading(s) as needed. The maximum score is 44. For the representative sample, Cronbach's alpha was .85, and criterion validity with the previous spring's TerraNova (CTB/McGraw-Hill, 1997)

Total Math score was .58 for the 844 students for whom we had TerraNova scores. Interscorer agreement, computed on 20% of protocols by two independent scorers, was .984.

*Complex word problems.* Complex Word Problems (Fuchs et al., 2003) comprises nine problems representing the same four problem types as the algorithmic word problems within more complex contexts: (a) adding multiple quantities of items with different prices, with information presented in bulleted format and with a selection response format; (b) adding multiple quantities of items with different prices, also asking for money left at the end; (c) a step-up function problem with irrelevant information; (d) a step-up function that requires students to compare the prices of two packaging options; (e) a half problem using the words *share equally* instead of *half*; (f) a pictograph/adding problem asking for money left at the end; (g) a pictograph/adding problem comparing two quantities; (h) a problem with irrelevant information that combines multiple quantities with different prices and pictograph/adding; and (i) a problem with irrelevant information that combines multiple quantities with different prices and a step-up function. The tester reads each item aloud while students follow along on their own copies of the problems. The tester progresses to the next item when all but one or two students have their pencils down, indicating they are finished. Students can ask for rereading(s) as needed. The maximum score is 79. For the representative sample, Cronbach's alpha was .88, and criterion validity with the previous spring's TerraNova (CTB/McGraw-Hill, 1997) Total Math Score was .55 for the 844 students for whom we had TerraNova scores. Interscorer agreement, computed on 20% of protocols by two independent, blind scorers, was .983.

### Cognitive Dimensions

*Language.* Using three measures of language skill, we used a principal components factor analysis to create a weighted composite variable of language. Test of Language Development—Primary Grammatical Closure (Newcomer & Hammill, 1988) measures the ability to recognize, understand, and use English morphological forms. The examiner reads 30 sentences, one at a time. Each sentence has a missing word, and examinees earn 1 point for each sentence correctly completed. As reported by the test developers, reliability is .88 for 8-year-olds; the correlation with the Illinois Test of Psycholinguistic Ability Grammatical Closure is .88 for 8-year-olds. Coefficient alpha on the representative sample was .76. The Woodcock Diagnostic Reading Battery Listening Comprehension (Woodcock, 1997) measures the ability to understand sentences or passages. For 38 items, students supply the word missing from the end of each sentence or passage. The test begins with simple verbal analogies and associations and progresses to comprehension involving the ability to discern implications. Testing is discontinued after six consecutive errors. The score is the number of correct responses. As reported by the test developers, reliability is .80 at ages 5 to 18; the correlation with the Woodcock-Johnson Psycho-Educational Battery—Revised (Woodcock & Johnson, 1989) is .73. Coefficient alpha on the representative sample was .81. WASI Vocabulary (Wechsler, 1999) measures expressive vocabulary, verbal knowledge, and foundation of information with 42 items. The first four items present pictures; the student identifies the object in the picture. For remaining items, the tester says a word that the student defines.

Responses are awarded a score 0, 1, or 2 depending on quality. Testing is discontinued after five consecutive scores of 0. The score is the total number of points. As reported by Zhu (1999), split-half reliability is .86 to .87 at ages 6 to 7; the correlation with the Wechsler Intelligence Scale for Children—III Full Scale IQ is .72. Coefficient alpha on the representative sample was .78.

*Semantic retrieval fluency.* WJ-III Retrieval Fluency (Woodcock et al., 2001) asks examinees to recall related items, within categories, for 1 min per category. Examinees earn credit for each nonduplicated answer. As reported by the test developers, reliability is .78 for 8-year-olds.

*Concept formation.* WJ-III Concept Formation (Woodcock et al., 2001) asks examinees to identify the rules for concepts when shown illustrations of instances and noninstances of the concept. Examinees earn credit by correctly identifying the rule that governs each concept. Cutoff points determine the ceiling. The score is the number of correct responses. As reported by the test developers, reliability is .93 for 8-year-olds. Coefficient alpha on the representative sample was .82.

*Nonverbal problem solving.* WASI Matrix Reasoning (Wechsler, 1999) measures nonverbal reasoning with four types of tasks: pattern completion, classification, analogy, and serial reasoning. Examinees look at a matrix from which a section is missing and complete the matrix by saying the number of or pointing to one of five response options. Examinees earn points by identifying the correct missing piece of the matrix. Testing is discontinued after four errors on five consecutive items or after four consecutive errors. The score is the number of correct responses. As reported by the test developer, reliability is .94 for 8-year-olds; the correlation with the Wechsler Intelligence Scale for Children—III Full Scale IQ is .66. Coefficient alpha on the representative sample was .76.

*Working memory.* With the Working Memory Test Battery for Children Listening Recall (Pickering & Gathercole, 2001), a measure of verbal working memory, the tester says a series of short sentences, only some of which make sense. The student indicates whether each sentence is true or false. After all sentences in a trial (i.e., one to six sentences) are heard and determined to be true or false, the student recalls the final word of each sentence in the order presented. The student earns 1 point for each sequence of final words recalled correctly in the right order, and the score is the total of correct sequences. Testing is discontinued when the student makes three or more errors in any block of items. As reported by Pickering and Gathercole, test-retest reliability is .93. Coefficient alpha on the representative sample was .72. With WJ-III Numbers Reversed (Woodcock et al., 2001), a measure of numerical working memory, the tester says a string of random numbers; the student says the series backwards. Item difficulty increases as more numbers are added to the series. Students earn credit by repeating the numbers correctly in the opposite order. As reported by the test developers, reliability is .86 for 8-year-olds. Coefficient alpha on the representative sample was .84.

*Word identification skill.* The Woodcock Reading Mastery Tests—Revised Word Identification (Woodcock, 1998) measures real-word reading ability with 100 words arranged in order of difficulty. Students read words aloud. Testing is discontinued after six consecutive errors at the end of a page. The score is the number of correct items. As reported by Woodcock, split-half reliability is .98. Coefficient alpha on the representative sample was .87.

**Attentive behavior.** The SWAN is an 18-item teacher rating scale (www.adhd.net). Items from the *Diagnostic and Statistical Manual of Mental Disorders* (4th ed.; American Psychiatric Association, 1994) criteria for attention-deficit/hyperactivity disorder are included for inattention (largely distractibility; Items 1–9) and hyperactivity/impulsivity (Items 10–18). Items are rated on a scale of 1 to 7 (1 = *far below*, 2 = *below*, 3 = *slightly below*, 4 = *average*, 5 = *slightly above*, 6 = *above*, 7 = *far above*). In the present study, we report data for the inattentive behavior subscale. Using the nine relevant items, we used a principal components factor analysis to create a weighted composite variable of attentive behavior, or the ability to maintain focus. (Because the principal components factor analysis yielded only one factor, no rotation was necessary.) The SWAN has been shown to correlate well with other dimensional assessments of behavior related to inattention (www.adhd.net). Coefficient alpha on the representative sample was .96.

**Processing speed.** WJ-III Visual Matching (Woodcock et al., 2001) measures processing speed by asking examinees to locate and circle two identical numbers in rows of six numbers. Examinees have 3 min to complete 60 rows and earn credit by correctly circling the matching numbers in each row. As reported by the test developer, reliability is .91 for 8-year-olds.

## Data Analysis and Results

### Variable Transformations

In Table 1, we show means, standard deviations, and correlations for the representative sample of 924 students on computation, problem solving, and nine cognitive dimensions (language, semantic retrieval fluency, concept formation, matrix reasoning, verbal working memory, numerical working memory, word identification, attentive behavior, and processing speed). Based on the entire sample of 924 students, we transformed raw scores for each of the three computation and each of the four problem solving measures to *z* scores ( $M = 0.00$ ,  $SD = 1.00$ ). For dimensions with more than one indicator (computation, problem solving, language, and attention), we used SAS PROC FACTOR to estimate factor scores, using squared multiple correlations as the communalities.

### Preliminary Analyses: Screening for Outliers and Nonlinearity and Regressions on the Representative Sample

To identify potential outliers, we plotted the bivariate relations of both problem solving and computation with each cognitive variable. We identified five outlier values whose cases we eliminated from further analyses. Then, to investigate the shape of the relations, we examined the bivariate relations between each math outcome and each cognitive variable. We used linear and quadratic forms of each predictor to investigate the functional relation. Any significant quadratic relations between cognitive dimension and math outcome were marked for inclusion in the full regression analysis. We found significant (although not substantial) nonlinearity between problem solving and computation when predicting computation from problem solving (but not when predicting problem solving from computation). So, in the full regression predict-

ing computation from problem solving, we included the quadratic term for problem solving.

We then completed regression analyses to examine the relation of each math outcome with the nine cognitive dimensions using the entire sample. When the quadratic relation between a cognitive dimension and a math outcome was significant (see above), we retained both the linear and quadratic relations within the full model. (We note that significant nonlinear relations between the cognitive variables and the math outcomes were trivial.) For each math outcome, we also investigated the interaction of the cognitive variables with the math outcome variable we were controlling. For example, when predicting computation, we entered problem solving, all nine cognitive variables, any significant quadratic relations (including the quadratic relation for problem solving), and the product vectors of each cognitive variable with problem solving. We did this to determine whether the relation of the cognitive variables with computation was consistent over the range of problem solving. We found that the block of interaction vectors did not add significantly for either math outcome and deleted the product vectors from the model. Finally, for each math outcome, we ran a pruned model, the variables for which neither the linear nor quadratic relation in the full regression model was significant. In Table 2, we present the results of the full and pruned models predicting computation performance. In Table 3, we present findings for the prediction of problem-solving performance. As shown, after we controlled for problem-solving skill in the prediction of computational skill, significant cognitive predictors were word identification, attentive behavior, processing speed, as well as the quadratic relation for numerical working memory. By contrast, after we controlled for computational skill in the prediction of problem-solving skill, significant cognitive predictors were language, concept formation, matrix reasoning, numerical working memory, as well as the quadratic relation for language and attentive behavior.

### Difficulty Status Group Formation

Because the major focus of the present study was to extend understanding about difficulty in computation versus problem solving and because the regressions only informed about the effect of each variable when the other variables are controlled at their means, it was important to examine performance specifically at the lower ranges of performance on the math outcomes. To establish extreme groups impaired on computation, problem solving, or both, we designated math difficulty in the following manner. Any student who scored above the 40th percentile on the problem-solving factor score and above the 40th percentile on the computation factor score was designated as having no difficulty (ND). Any student who scored below the 15th percentile on the computation factor score but above the 40th percentile on the problem-solving factor score was designated as having computational difficulty (CD). Any student who scored below the 15th percentile on the problem-solving factor score but above the 40th percentile on the computation factor score was designated as having problem-solving difficulty (PD). Any student who scored below the 15th percentile on the problem-solving factor score and below the 15th percentile on the computation factor score was designated as having computation and problem-solving difficulty (CPD). This placed 372 students in the buffer zone (i.e., scoring between the 16th and 39th percentiles on either or both math outcome) and

\*  $p < .05$ . \*\*\*  $p < .001$ .

resulted in 415 ND, 35 CD, 33 PD, and 64 CPD. All remaining analyses were conducted on this subset of 547 students classified as ND, CD, PD, or CPD (i.e., not in the buffer zone). Because academic performance occurs on a continuum, cutoffs for denoting difficulty or lack thereof are necessarily arbitrary, as is the designation of learning disability in the schools. The 40th percentile is used commonly in the research literature as a cut-point for designating lack of difficulty. Cutoffs for designating difficulty or disability vary more in the literature. We selected the 15th percentile because it is useful for understanding disability as practiced in the schools. In Table 4, we show standard score means and standard deviations for the nationally normed math variables we had available and for the cognitive dimensions on which we had nationally normed data.

### Sociodemographic Comparisons

In Table 5, we show frequencies for gender, subsidized lunch, and ethnicity by difficulty status. For each variable, we partitioned the contingency tables to run a series of chi-square tests for determining (a) whether ND differed from students with difficulty (ND vs. CD/PD/CPD), (b) whether CD differed from either variant of problem-solving difficulty (CD vs. PD/CPD), and (c) whether the two variants of problem-solving difficulty differed (PD vs. CPD). To control for multiple comparisons, we adjusted the value of alpha by the number of contrasts on each index (i.e., tested at  $p = .05 / 3 = .0167$ ). There was no significant relation between

gender and math difficulty status:  $\chi^2(1, N = 547) = 0.02, ns$ ;  $\chi^2(1, N = 132) = 0.01, ns$ ; and  $\chi^2(1, N = 97) = 0.50, ns$ , for the three contrasts, respectively. For the proportion of subsidized lunch, however, an interesting set of relations emerged. As might be anticipated, students without math difficulty were significantly less likely to receive subsidized lunch than were students with math difficulty,  $\chi^2(1, N = 547) = 6.82, p = .009$ . More interesting is the fact that students with computational difficulty were significantly less likely to receive subsidized lunch than were students with problem-solving difficulty (PD or CPD),  $\chi^2(1, N = 132) = 7.01, p = .008$ , even though students with PD alone and those with CPD were comparably likely to receive subsidized lunch,  $\chi^2(1, N = 97) = 0.46, p = .50$ . The same pattern emerged for ethnicity. The distribution of ethnicity differed between students with and without difficulty,  $\chi^2(5, N = 547) = 33.13, p < .001$ . The distribution of ethnicity also differed for students with CD versus those with problem-solving difficulty (PD or CPD),  $\chi^2(5, N = 132) = 22.89, p < .001$ , even though students with the two variants of problem-solving difficulty (PD vs. CPD) were similarly distributed across the ethnicity categories,  $\chi^2(5, N = 97) = 7.71, p = .17$ .

### Group Comparisons on Cognitive Dimensions

Table 6 presents z-score means and standard deviations, by difficulty status, on the computation and problem-solving factor scores and on language (factor score), semantic retrieval fluency, concept formation, matrix reasoning, verbal working memory,

numerical working memory, word identification, attentive behavior (factor score), and processing speed.

**Preliminary analysis of clustering effects.** Before choosing an analytic model, we examined the extent of clustering of children in classes and schools. With clustering, the independence assumption of analysis of variance may be violated, possibly leading to spurious significance levels (Raudenbush & Bryk, 2002). Strong clustering would necessitate a multilevel model rather than a repeated measures approach. Variance components were estimated with SAS PROC MIXED (Littell, Milliken, Stroup, Wolfinger, & Schabenger, 2006). The resulting intraclass correlations showed how much of the total variance in the variables of interest (i.e., the nine cognitive dimensions) was explained by the clustering of children in classroom and school. The effect for school explained 0% of the variance, and the effect for classroom (nested in school) explained less than 5%. Raudenbush and Liu's (2000) ad hoc standards deem 5%, 10%, and 15% as small, medium, and large.

**Overall analysis.** Because the intraclass correlations in this database were small to nonexistent, we conducted an initial profile analysis using a two-way analysis of variance. The between-subjects factor was math difficulty status (ND vs. CD vs. PD vs. CPD); the within-subjects factor was cognitive dimension ( $z$  score on language vs. semantic retrieval fluency vs. concept formation vs. matrix reasoning vs. verbal working memory vs. numerical working memory vs. word identification vs. attentive behavior vs. processing speed). The interaction between math difficulty status and cognitive dimension was significant,  $F(24, 4337) = 4.67$ ,  $p < .0001$ .

To help interpret the interaction between math difficulty status and cognitive dimension, we plotted  $z$  scores on the nine cognitive dimensions for each of the four difficulty status groups (see Figure 1). As shown, the ND and CD groups performed at a higher level than did the PD and CPD groups. In addition, the difficulty status by cognitive dimension interaction appeared to be evident in the variations in the profile shape across the nine cognitive dimensions as a function of the difficulty status group.

**Univariate follow-ups to the interaction.** Because the elevation effects in Figure 1 were striking and because many studies have compared univariate differences among math difficulty groups, we initially conducted follow-up tests using Fisher's least significant difference, with math difficulty status as the factor (Seaman, Levin, & Serlin, 1991). Alpha was adjusted for six contrasts per measure, comparing each difficulty status group to all others ( $p = .05 / 6 = .008$ ). Results of these follow-up tests appear under the labels on the horizontal axis in Figure 1. Symbols for the four groups (see key) appear under each cognitive dimension. Groups joined by a horizontal line were not significantly different from one another. The univariate test on each cognitive dimension was significant ( $p < .0001$ ). To help evaluate the magnitude of the univariate differences, we computed effect sizes for each variable (see Table 7) by dividing the difference between group means by the standard deviation pooled across the two groups in the comparison (Hedges & Olkin, 1985). The complicated pattern of differences that emerged is addressed in the Discussion.

**Profile analysis of shape effects.** The interpretation of a pattern like the one shown in Figure 1 is complicated. The univariate

Standard scores are *M* = 100, *SD* = 15, except vocabulary and matrix reasoning, for which *M* = 50 and *SD* = 10. ND = no difficulty; CD = computational difficulty; PD = problem-solving difficulty; CPD = computational and problem-solving difficulty.

<sup>a</sup> Woodcock-Johnson III Tests of Achievement (WJ-III) Applied Problems. Applied Problems assesses a variety of math domains with only a limited number of word problems assessed in the third-grade range. <sup>b</sup> Test of Language Development-Primary Grammatic Closure. <sup>c</sup> Woodcock Diagnostic Reading Battery Listening Comprehension. <sup>d</sup> Wechsler Abbreviated Scale of Intelligence (WASI) Vocabulary. <sup>e</sup> WJ-III Retrieval Fluency. <sup>f</sup> WJ-III Concept Formation. <sup>g</sup> WASI Matrix Reasoning. <sup>h</sup> Working Memory Test Battery for Children Listening Recall. <sup>i</sup> WJ-III Numbers Reversed. <sup>j</sup> Woodcock Reading Mastery Tests-Revised Word Identification. <sup>k</sup> WJ-III Visual Matching.

tests do not account for relations among the cognitive dimensions, and they confound level and measure effects. A traditional multivariate analysis of variance determines how a set of measures can be combined into a set of  $K - 1$  univariate composites (discriminant functions), which maximally separates groups (Bernstein, Garbin, & Teng, 1988; Harris, 1975). However, each composite comprises elements that involve differences not only in elevation but also in shape, both of which seem apparent in the profiles shown in Figure 1. By contrast, a multivariate profile analysis accounts for correlations among cognitive dimensions and decomposes the univariate composites into components representing elevation, flatness, and shape. The elevation effects are differences among groups averaged across the dimensions. Flatness effects are

differences in dimensions averaged across groups; they indicate whether the profile measures vary or can be represented as a relatively straight line (because we used *z* scores, we did not anticipate flatness effects). When profiles differ in shape, which is analogous to the Difficulty Status  $\times$  Dimension interaction already documented, differences among groups vary depending on cognitive dimension, in which case the elevation and flatness components are not interesting.

Thus, we used multivariate profile analysis to conduct four planned contrasts to explore how the profiles of the math difficulty groups differed. In these contrasts, we compared the ND group to the specific computational difficulty group and then in turn compared the specific computational difficulty group to each of the

Table 5  
Demographics by Difficulty Status

groups involving problem-solving difficulty, thereby reducing the need to compare the ND and problem-solving difficulty groups directly (especially given that the ND group performed at a much higher level than the CPD and PD groups, as shown in Figure 1). We also compared the specific problem-solving difficulty group to the group that manifested both forms of difficulty. To control for Type 1 error (given four planned contrasts), we adjusted the critical value of alpha to .0125 (.05 / 4); however, because the power for each comparison differed, effect sizes (eta-squared) were also considered.

Although separate effects for the elevation, flatness, and shape effects might be explored in a profile analysis approach, the large interaction already documented in the univariate analysis between difficulty status and cognitive dimension mitigated against pursuing elevation or flatness effects. Table 8 presents the interaction contrasts exploring the shape effects. As shown, only the contrasts for ND versus CD and for CD versus PD met the critical alpha level. Although the contrasts between PD and CPD and between CD and CPD did not meet the critical alpha level, the effect sizes (both ~0.15) were slightly larger than for the ND versus CD contrast (0.08), the latter having more power. Effect sizes were in the small to medium range.

In interpreting the shape effects, we note that the overall tests for elevation, flatness, and shape are not dependent on the ordering of the dimensions. However, interpretation of individual dimensions may depend on the ordering and the location of pairs of dimen-

sions in the profile. To determine how profile dimensions contribute to the interaction regardless of the ordering of the dimensions, we followed a commonly recommended procedure for the interpretation of profile analysis multivariate analysis of variance: inspection of the canonical structure matrix (Harris, 1975). In following up the shape effect, it is also necessary to remove the effect of elevation (Bernstein et al., 1988; Fletcher et al., 1994). This was done by computing the residuals in a model, which included only the main effects of group and cognitive dimension; the result reduced the elevation of each group to approximately zero. Any variation among group means on the cognitive variables is then due only to the effect of shape.

Figure 2 shows the elevation-adjusted shape profile for each of the four groups along the nine cognitive dimensions. Note that the relation of the groups on the *y*-axis differs substantially from the relations manifested in Figure 1. This is because the elevation differences that dominated Figure 1 have been removed in Figure 2. In Table 9, we present the canonical structure matrix for each of the four planned contrasts. Within the canonical structure matrix, simple correlations are computed for each variable with the discriminant function representing the multivariate effect for shape, adjusted for elevation (Huberty, 1975). The positive or negative value of the correlations reflects the pattern of mean differences between the contrasted groups. For interpretive purposes, we consider both the magnitude and the direction of these correlations as well as the significance of the univariate test (*F*

Figure 1. *z* scores on nine cognitive dimensions by difficulty status. WM = working memory; ID = identification.

value) associated with each cognitive variable for each pair of contrasts (see asterisks in Table 9, where the critical *p* value has been adjusted to .006 to account for nine univariate dimensions).

As reflected in the canonical structure correlations shown in Table 9, the contrast between the ND and CD groups was accounted for by language (−.44), attentive behavior (.60), and processing speed (.32), which were more heavily weighted than other variables. Accordingly, in Figure 2, the difference in language (positive direction for CD relative to other dimensions), attentive behavior (negative direction for CD relative to other dimensions), and processing speed (negative direction for CD relative to other dimensions) most clearly differentiates the shape of the ND and CD profiles. Among language, attentive behavior, and processing speed, attentive behavior was the most reliable correlate of the shape effect across different methods of interpreting the contributions of the dimensions.

As might be expected, therefore, for the comparison between the PD and CPD groups, Table 9 shows the highest canonical structure coefficients for attentive behavior (.54) and processing speed (.44). In Figure 2, these differences in attentive behavior (negative direction for CPD relative to most other dimensions) and processing speed (positive direction for PD relative to most other dimensions) are striking aspects of the profile and also clearly contrast with the profile for the CPD group, in which attentive behavior was a negative dimension and processing speed is neutral. Again, attentive behavior was the most reliable correlate of the shape effect across different methods of interpreting the contributions of the dimensions.

By contrast, for the comparison between PD and CD, language (−.70) and processing speed (.51) were the variables contributing

to the shape effect and reflect the negative direction of language relative to other dimensions for the PD group and the positive direction in language relative to other dimensions for the CD group. In contrast, processing speed was a negative dimension for the CD group but positive for the PD group. Figure 2 shows that semantic retrieval fluency was also positive in the PD group, a likely suppressor effect given the large standardized coefficient for semantic retrieval fluency (.74). Language was the most reliable correlate of the shape effect across different methods of interpreting the contributions of the dimensions. Finally, and in keeping with the contrast between PD and CD, the cognitive dimension accounting for the contrast between the CPD and CD groups was language (−.72). The standardized coefficients showed a similar pattern. Again, this variable moved in opposite directions in the profiles for the two groups (see Figure 2).

## Discussion

The purposes of this study were to explore the overlap between difficulty with two aspects of primary-grade mathematical cognition—computation and problem solving—and to examine how demographic and cognitive profiles differ among subgroups with difficulty in one, the other, both, or neither. The goal was to gain insight into whether these domains are shared or distinct aspects of mathematical cognition in extreme groups. This issue is not only theoretically important but also has implications in terms of identifying math disability, as specified in the 2004 reauthorization of the Individuals with Disabilities Education Act, and for designing effective methods for preventing and remediating math difficulty.

Table 7  
Effect Sizes (in Absolute Values) for Math Variables and Cognitive Dimensions as a Function of Difficulty Status

Variable	Contrast					
	ND vs.			CD vs.		PD vs. CPD
	CD	PD	CPD	PD	CPD

With respect to overlap, results revealed that difficulty in one domain did not necessarily align with difficulty in the other. This is understandable because correlations between computational and problem-solving skill, as demonstrated elsewhere (e.g., Fuchs et al., 2006; Swanson & Beebe-Frankenberger, 2004), were only moderate, ranging from .30 to .49. In fact, difficulty occurred in a single math domain as frequently as across math domains. Moreover, specific difficulty was distributed across the two domains with almost identical prevalence.

In a related way, the demographic profiles of the groups also suggest that performance in these two domains of mathematical cognition may be distinct. The demographic profiles of students with specific computational difficulty, in terms of poverty and ethnic background, were more similar to those of students without difficulty than to those of students with problem-solving difficulty or with concurrent difficulty. This suggests that the contextual variables associated with poverty or race exert little effect over the development of computational difficulty. By contrast, students with problem-solving difficulty were significantly poorer and disproportionately more likely to be African American compared to students with specific computational difficulty. This was true regardless of whether problem-solving deficits occurred alone or in combination with computational deficits, with no significant

demographic differences between students experiencing specific problem-solving difficulty and those experiencing concurrent problem-solving and computational difficulty. This finding indicates that early or ongoing experience outside of school may account for variance in building a strong foundation for mathematical problem solving.

To identify what kinds of experience outside of school may be key, it is useful to consider analysis of the cognitive dimensions. The regression analyses indicate that a different set of cognitive predictors is associated with the math outcomes, suggesting that these two domains of mathematical cognition may be distinct. However, because the focus of the present study was to extend understanding about difficulty with computation versus problem solving, and because the regressions only inform about the effect of each variable when the other variables are controlled at their means, it is important to examine performance specifically at the lower ranges of performance on the math outcomes.

The univariate profile analyses, which addressed mean differences among difficulty status groups on each cognitive dimension, indicate that language and word identification clearly distinguished problem-solving from computational difficulty. Students with problem-solving difficulty, regardless of whether the problem-solving difficulty occurred alone or in combination with computational difficulty, scored reliably lower than students with neither form of difficulty and lower than those who experienced computational deficits alone. Moreover, students with computational difficulty were statistically indistinguishable from students without difficulty, and students with problem-solving difficulty alone were statistically comparable to students with problem-solving difficulty that occurred in combination with computational difficulty. Two additional variables, concept formation and matrix reasoning, also served to distinguish problem-solving difficulty from computational difficulty (with PD and CPD comparable to each other, and both lower than students with CD and ND, although on these dimensions, students with specific computational difficulty were reliably lower performing than students without difficulty).

It is therefore interesting to consider these abilities in light of the major distinction between mathematical computation and problem solving: the addition of linguistic information that requires individuals to construct a problem model. That is, whereas a computation problem is already set up for solution, a word problem requires students to use text to identify missing information, construct the number sentence, and derive the calculation problem for finding the missing information. This transparent difference would

Table 8  
Math Difficulty Status × Cognitive Dimension Interactions for Four Planned Comparison

seem to alter the nature of the task, and findings corroborate such a hypothesis.

With respect to the contribution of reading skill, although word problems were read aloud to students, with repeated opportunities for rereading whenever students requested, students had the written problem available until they completed it; so, we note that independent, skilled reading may support continuous access to text. In a different way, because the development of word identification skill is facilitated by vocabulary knowledge (cf. Perfetti, 1992), the link between word identification and problem-solving skill suggests that language may play a role in math problem solving. This finding was in fact documented in the univariate analyses. It stands to reason

that the ability to make sense of language, as reflected indirectly by word recognition skill and as reflected directly by our language factor score (i.e., grammatic closure, listening comprehension, and vocabulary), should help students cope with narratives in the service of building problem models, and findings corroborate previous work about the role language plays in problem-solving skill (e.g., Fuchs et al., 2006). It also makes sense that nonverbal problem-solving skill, as reflected in concept formation and matrix reasoning, should underlie mathematical problem-solving skill. This corroborates previous work (Fuchs et al., 2005, 2006) and is interpretable because mathematical problem solving requires students not only to build a problem model but also to distinguish relevant from irrelevant

information and to determine how numerical quantities fit into the slots of the problem model (cf. Kintsch & Greeno, 1985).

For the remaining cognitive dimensions, the univariate results were less clear. On verbal and numerical working memory, the performance of the three difficulty groups was indistinguishable. However, on numerical working memory (but not on verbal working memory), students with specific computational difficulty performed comparably to their peers without difficulty.

In terms of working memory, or the capacity to maintain target memory items while processing an additional task (Daneman & Carpenter, 1980), a body of work has established links with computation (Fuchs et al., 2005; Geary et al., 1991; Hitch & McAuley, 1991; Siegel & Linder, 1984; Webster, 1979; Wilson & Swanson, 2001) and problem solving (e.g., Fuchs et al., 2005; LeBlanc & Weber-Russell, 1996; Passolunghi & Siegel, 2004; Swanson & Beebe-Frankenberger, 2004; Swanson & Sachse-Lee, 2001). Although other studies have raised questions about the tenability of this association (e.g., Fuchs et al., 2006; Swanson et al., 1993), the univariate results of the present study corroborate a role for working memory, verbal as well as numerical, in both computational and problem-solving difficulty. For computation, students must hold terms and operators in working memory while using various counting strategies to arrive at the correct answer. Over time, repeated associations for the problem stem and its answer, achieved via successful counting, result in representations in long-term memory, which in turn facilitate fluent procedural computation. With respect to word problems, as described by Kintsch and Greeno (1985), when processing a problem narrative, students formulate new sets to construct a problem model. When a proposition that triggers a set-building strategy is completed, the appropriate set is formed and the relevant propositions are assigned their places in the various slots of the set schema. As new sets are formed, previous sets that had been active in the memory buffer are displaced, illustrating the potential importance of working memory. Our univariate analyses lend empirical support for the contribution of working memory to both aspects of mathematical cognition: computation and problem solving. It is important to note, however, that the multivariate profile analyses indicate that working memory is primarily related to elevation (severity), not to shape.

In any case, results of the univariate analyses suggest a pattern of more pervasive cognitive involvement for problem-solving difficulty. Yet, because univariate analyses fail to account for relations among the cognitive dimensions and because in the univariate analyses, elevation and shape are confounded, it is important to consider results of the multivariate profile analyses. At a general level, by explicating the patterns of cognitive abilities associated with computational and problem-solving difficulty, the shape analyses highlight two important notions: (a) that computational difficulty may be distinct from problem-solving difficulty and (b) that the cognitive dimensions associated with performance in a single math domain may also be associated with both computation and problem solving when difficulties occur concurrently. At the same time, the multivariate profile results, which isolate the effects of shape from the effects of elevation, serve to pinpoint more specifically and narrowly which cognitive differences between groups matter. In this way, results demonstrate the need to rely on multivariate, rather than univariate, approaches in the study of mathematics.

Within the multivariate interpretations of the profile analyses, three cognitive dimensions emerged as central to the distinction between computational and problem-solving difficulty. The dominant role of language deficits was substantiated for problem-solving difficulty. Language was the cognitive dimension that served to distinguish the specific problem-solving difficulty group from the specific computational difficulty group and to distinguish the group with concurrent difficulty across problem solving and computation again from the specific computational difficulty group. By contrast, the dominant roles of attentive behavior and processing speed were revealed for computational difficulty, serving to distinguish the specific computational difficulty group from the group without either form of difficulty and to distinguish the group with concurrent difficulty across computation and problem solving from the group with specific problem-solving difficulty.

In the preceding discussion about the univariate analyses, we already considered the role of language in problem solving, but what about the role of attentive behavior and processing speed in computation, which became evident only in the multivariate analyses? Within the univariate analyses, a step-down pattern occurred for attentive behavior, whereby students without difficulty were rated more favorably than the other three groups; students with specific computational difficulty were rated similarly as students with specific problem-solving difficulty but more attentive than students with concurrent difficulty; and students with specific problem-solving difficulty were deemed similarly attentive as students with concurrent difficulty. This ordering, which suggests greater cognitive involvement for problem-solving deficits, is based entirely on elevation differences among groups. By contrast, the multivariate analyses specifically consider the shape (i.e., the profile) by removing the elevation effects. These multivariate profile analyses demonstrate that attentive behavior is implicated in computational but not problem-solving difficulty. Few studies have considered attentive behavior as a predictor of computational skill, but some previous work has suggested its role (e.g., Fuchs et al., 2005, 2006). Moreover, Swanson (2006) recently substantiated the role of inhibitory control, a form of attention, in the development of computational but not problem-solving skill.

At least two explanations seem possible for the role of attentive behavior in computational difficulty. First, attentive behavior may create the opportunity to persevere with the serial execution required for computational math (Luria, 1980) and thereby enhance performance and improve students' responsiveness to instruction. Alternatively, it is possible that teacher ratings of attentive behavior are clouded by students' academic performance and therefore serve as a proxy for achievement rather than indexing attention. Cirino, Ewing-Cobbs, Barnes, Fuchs, and Fletcher (2007) found that although attentive behavior accounts for unique variance in mathematics performance, removing variance due to behavioral ratings of attention does not alter the relations of cognitive measures and mathematical cognition. Present findings, in which attentive behavior was implicated in specific computational difficulty but not specific problem-solving difficulty, reduce the plausibility that teacher ratings simply serve as a proxy for academic achievement and instead provide the basis for hypothesizing that attentive behavior plays a role in computation and for explor-

ing the underlying nature of the relation with alternative measures of attention.

In terms of processing speed, previous work has suggested that processing speed underlies fluency with math facts. For example, Bull and Johnston (1997) found that processing speed subsumed all of the variance in 7-year-olds' arithmetic skill while controlling for word reading ability, item identification, and short-term memory. Processing speed may facilitate counting speed so that as young children gain speed in counting sets to figure sums and differences, problems are successfully paired with their answers in working memory before decay sets in, such that associations in long-term memory are established (e.g., Geary et al., 1991; Le-maire & Siegler, 1995). In addition, Fuchs et al. (2006) demonstrated that processing speed accounted for unique variance in simple arithmetic but not in mathematical problem solving once the relation between processing speed and arithmetic had been accounted for.

In sum, findings lend support for the hypothesis that computation and problem solving may represent distinct domains of mathematical cognition within students at the lower ranges of performance as might be identified with mathematics learning disabilities in the schools. This lends empirical support for the distinction between computational and mathematics problem-solving learning disabilities specified in the 2004 reauthorization of the Individuals with Disabilities Education Act. Results also suggest that poverty and language play critical roles in the development of problem-solving difficulty and that inattentive behavior and poor processing speed may inhibit the development of computational skill. In addition, despite the more substantial math deficits evidenced for students with concurrent difficulty (i.e., an effect size of 0.86 favoring the computational skill of CD over CPD and an effect size of 0.68 favoring the problem-solving skill of PD over CPD), the cognitive deficiencies associated with math performance in a single domain are also apparent when difficulties occur in both domains: for computation, attention and processing speed (as revealed for CD and for CPD); for problem solving, language (as revealed for PD and for CPD). Similarly, poverty or race is associated with problem-solving difficulty, whether it occurs alone or in combination with computational difficulty, and therefore corroborates the relation between language and these sociodemographic variables. Together, these findings suggest that concurrent difficulty with computation and problem solving may not be a unique form of math disability but represents a comorbid association of difficulties in both domains. Additional research should continue to investigate these issues as well as explore the possible role of other cognitive dimensions, including reading comprehension. Matching groups of students on their areas of math strength may also be a productive line of related work. Further work is also needed using larger samples to yield difficulty status groups with greater numbers of students and using more restrictive cutoffs for denoting difficulty that correspond even more closely to the criteria employed to designate children in schools as having mathematics learning disabilities. In addition, related work using different strategies for measuring computational skill, problem-solving skill, and the nine cognitive dimensions is required to corroborate effects. Furthermore and more generally, present study findings indicate that multivariate analytic approaches are required to untangle the

role of cognitive abilities underlying the development of mathematical skill.

In the meantime, however, we caution practitioners about the potential need to consider computational skill and problem-solving skill separately in diagnosing and instructing students with learning disabilities. We also note that models of mathematical competence should expand focus on mathematical problem solving and explicitly consider the abilities that underlie the development of this form of mathematical competence. Moreover, findings support the importance of studying instructional procedures that may enhance performance specifically in the area of mathematical problem solving, separate from the issue of how to promote computational skill. Finally, the critical importance of assessing computational and problem-solving skills separately for the presence of math difficulties is apparent. Many mathematics assessments are generic and do not adequately attend to the differentiation of these dimensions of mathematical cognition.

# Mathematical Competencies in Children With Different Types of Learning Difficulties

Ulf Andersson  
Linköping University

The mathematical performance of 182 third and fourth graders in 8 different areas of mathematics was examined. The children belonged to 4 achievement groups: children with mathematic difficulties (MD only), children with both mathematic and reading difficulties (MD–RD), children with reading difficulties (RD only), and normally achieving children (control group). Both MD groups performed worse than the normally achieving children in all but 1 area, place value knowledge. The MD-only and the MD–RD children performed equally in all areas of mathematics. The RD-only group performed at the same level as the control group on all areas of mathematics. The study provides further evidence that fact retrieval deficits are a cardinal characteristic of children with MD. The MD children's substantial difficulties with mathematic word problem solving can be attributed to several processes involved in problem solving. Besides poor skills in multidigit calculation, arithmetic fact retrieval, and poor understanding of calculation principles, children with MD might have deficits related to specific problem-solving processes such as establishing a problem representation and developing a solution plan.

**Keywords:** mathematical difficulties, reading difficulties, calculation, mathematic problem solving, telling time

During the past 10 to 15 years, an increasing number of studies have been carried out on children with difficulties in mathematics (Geary & Brown, 1991; Geary, Brown, & Samaranayake, 1991; Gonzalez & Espinel, 2002; Russell & Ginsburg, 1984; Swanson & Beebe-Frankenberger, 2004). However, most of these studies have focused on basic mathematical skills (i.e., arithmetic fact retrieval, calculation skill, and simple arithmetic word problem solving; Geary, Hamson, & Hoard, 2000; Geary, Hoard, & Hamson, 1999; Ostad, 1997, 1998), whereas considerably less research has focused on other domains of mathematics such as approximate arithmetic, comprehension of calculation principles, and mathematical word problem solving (Fuchs & Fuchs, 2002; Hanich, Jordan, Kaplan, & Dick, 2001; Russell & Ginsburg, 1984).

The present study was an attempt to extend existing research by examining multiple areas of mathematics in groups of children with different types of learning difficulties. Up to now, only four studies have examined multiple areas of mathematics in groups of children with learning difficulties (Hanich et al., 2001; Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003; Russell & Ginsburg, 1984). This type of research is necessary if one is to be able to provide a more comprehensive picture of mathematical difficulties (MD) in children, for instance by identifying core deficits. It is quite possible that children with MD might display normal skill levels in some areas of mathematics, whereas their skill levels

in other areas are severely impaired (cf. Dowker, 2005; Ginsburg, 1997). By examining multiple areas of mathematics, it should also be possible to study whether difficulties in one area are due to problems in another area; for example, problems with multidigit calculation might be attributed to deficits in arithmetic fact retrieval.

## Different Domains of Mathematics

The general theoretical assumption of the present study was that mathematical competence consists of multiple abilities that are taught and learned in a hierarchical manner (Aunola, Leskinen, Lerkkanen, & Nurmi, 2004; Dowker, 2005; Geary, 1994). That is, basic skills such as more/less comparisons of small quantities and counting are prerequisites for solving basic arithmetic tasks (e.g.,  $3 + 4 = 7$ ), first by means of counting procedures and later by direct retrieval of arithmetic facts from long-term memory (Baroody & Wilkins, 1999; Geary et al., 2000; Mazzocco & Thompson, 2005). More complex mathematic skills such as multidigit calculation and word problem solving are in turn facilitated by mastery of basic arithmetic operation; arithmetic facts retrieval; and conceptual understanding of place value, the base-10 number system, and calculation principles (Geary, 2004; Jordan, Hanich, & Uberti, 2003).

The present study examined eight areas of mathematics: arithmetic fact retrieval, written arithmetic calculation, approximate arithmetic, place value, calculation principles, one-step and multistep mathematic word problems, and telling time. These areas were selected because they have either direct or indirect relevance to the teaching of mathematics in the present age group of children (i.e., Grades 3 and 4). That is, all areas are emphasized in elementary school, with a particular focus on basic arithmetic (including arithmetic fact retrieval), place value, and written calculation in

Grades 1 and 2, and more focus on mathematic word problem solving in Grades 3 and 4. Thus, skills in areas such as fact retrieval and place value should be rather well developed in most children, whereas the ability to solve word problems should still be developing. Another reason for examining the present areas was that previous studies have shown that children in Grades 2 to 4 with MD display problems with almost all of these areas (Hanich et al., 2001; Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003; Jordan & Montani, 1997).

### Children With Specific Difficulties in Mathematics and Comorbid Reading Difficulties

When performing research on children with MD it is important to make a distinction between children with specific MD (MD only) and children with difficulties in both mathematics and reading, so-called comorbid mathematic and reading difficulties (MD–RD). This distinction is important because the functional and general cognitive characteristics of children with MD only and comorbid MD–RD differ (Andersson & Lyxell, 2007; Geary et al., 1991, 1999; Siegel & Ryan, 1989). Overall, children with comorbid MD–RD display more severe and global functional difficulties than children with MD only (Andersson & Lyxell, 2007; Fuchs & Fuchs, 2002; Jordan & Hanich, 2000; Jordan & Montani, 1997). Research has also indicated that children with MD–RD have a general working-memory deficit, whereas children with MD only have a specific working-memory deficit (Geary et al., 1991, 1999; Siegel & Ryan, 1989).

### Basic Arithmetic

Previous research focusing on basic arithmetic skills has shown that children with MD only and with comorbid MD–RD are slower, commit more errors, and employ developmentally immature counting procedures (e.g., counting all instead of counting on) when solving simple arithmetic problems ( $3 + 4$ ) by means of different counting strategies such as finger counting, verbal counting, or silent counting (Geary et al., 1999, 2000; Hanich et al., 2001; Russell & Ginsburg, 1984; see also Geary, 1993, 2004, for a review). Moreover, they do not follow the normal development of shifting from procedural problem-solving strategies (e.g., silent counting) to a memory-based problem-solving strategy. That is, they solve simple arithmetic problems ( $3 + 4$ ) by means of direct and automatic retrieval of arithmetic facts from long-term memory less frequently compared to children without MD. They often continue to employ procedural problem-solving strategies as their main solution strategies, and when they apply direct retrieval they are slow and commit many errors (Bull & Johnston, 1997; Geary et al., 1991; Jordan & Montani, 1997; Ostad, 1997, 1998; Siegler, 1988). These findings indicate that children with MD and MD–RD have procedural problems and problems with establishing memory representations regarding the associations between problems and answers to simple arithmetic problems in semantic long-term memory (Ashcraft, 1992; Geary, 1993). Lack of these representations, or difficulties in retrieving them, could prevent the child from developing the automation that is necessary in order to effectively solve complex (multidigit) arithmetic tasks (Ashcraft, 1992). This is because lack of automation will probably require more of the child's limited working-memory capacity, leaving less

capacity available for performing other aspects of arithmetic calculation, such as calculating and storing interim results and performing carrying or borrowing operations (Ashcraft, 1992, 1995; Geary, 2004).

Fact retrieval problems have been demonstrated from Grade 1 up to Grade 7 in children with MD, thus it seems that fact retrieval deficits are persistent and a cardinal characteristic of MD in children (Geary et al., 1999; Jordan, Hanich, & Kaplan, 2003; Ostad, 1997, 1998; Russell & Ginsburg, 1984). Although children with both MD only and MD–RD have fact retrieval problems and rely on backup strategies to a greater extent than normally achieving children, the MD-only group uses counting procedures more skillfully than the MD–RD children (Andersson & Lyxell, 2007; Geary et al., 2000; Hanich et al., 2001; Jordan & Montani, 1997). This indicates that the MD–RD group has more severe procedural problems preventing them from obtaining correct answers to simple arithmetic combinations by executing counting strategies (e.g., verbal counting). The more severe procedural problems in children with MD–RD might be related to a less developed conceptual understanding of counting principles (Geary, Bow-Thomas, & Yao, 1992; Geary et al., 1999). As working-memory resources support counting processes, it is also possible that the more global working-memory problems of the MD–RD children account for their problem with solving arithmetic combinations by means of verbal counting strategies (Geary, 1993, 2004; Geary et al., 1999; Logie & Baddeley, 1987; Passolunghi & Siegel, 2001).

In sum, a limitation of the studies described previously is that they almost exclusively have employed addition problems and to some extent subtraction problems, but not multiplication problems. In order to expand researchers' knowledge concerning fact retrieval problems in children with MD, the ability to retrieve multiplication facts should be examined, as children's problems might vary among operations.

### Mathematic Story Problem Solving

Most studies examining word problem solving in children with MD have used simple one-step arithmetic problems such as "Pete has 7 marbles. Sam gives him 5 more marbles. How many marbles does Pete have now?" or "Kate and Mark are playing marbles. Kate has 2 marbles. Mark gives her some more marbles. Now Kate has 6 marbles. How many marbles did Mark give her?" (e.g., Hanich et al., 2001; Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003; Jordan & Montani, 1997). The empirical picture of these studies demonstrates that children with MD or MD–RD in Grades 2, 3, and 4 have major difficulties with this type of word problem-solving task. However, children with MD–RD appear to have more severe difficulties in solving simple one-step arithmetic problems than children with MD only (e.g., Hanich et al., 2001; Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003; Jordan & Montani, 1997). For example, Jordan and Montani found that children with MD only obtained lower scores than normally achieving children in timed conditions but not in untimed conditions, whereas children with MD–RD obtained lower scores regardless of whether the task was timed or untimed compared to normally achieving children. Furthermore, in the untimed condition, MD–RD children were outperformed by MD-only children. According to Jordan and colleagues, these findings indicate that children with MD only have problems with problem-solving

speed, whereas MD–RD children seem to have difficulties with problem comprehension (Hanich et al., 2001; Jordan & Hanich, 2000; Jordan & Montani, 1997). This conclusion is supported by findings reported by Fuchs and Fuchs (2002).

A few researchers have also examined problem solving beyond simple arithmetic problems (Fuchs & Fuchs, 2002; Parmar, Cawley, & Frazita, 1996; Russell & Ginsburg, 1984). Russell and Ginsburg found that children with MD–RD performed on a par with controls on simple one-step problems but displayed considerable difficulties with multistep word problems and problems that involved irrelevant information. Parmar et al. reported similar findings from a study on children with mild forms of MD–RD across Grades 3 through 8. Fuchs and Fuchs compared the performance of fourth graders with MD only or MD–RD to normative data on three types of problem-solving tasks: one-step arithmetic problems, multistep complex story problems that included irrelevant information, and real-world story problems that included irrelevant information. They also separated operational ability and problem-solving ability by scoring on each dimension. Both groups with MD displayed large deficits on all three tasks, but the MD-only children performed overall better than the MD–RD children. However, on the arithmetic story problems the MD-only group outperformed the MD–RD group on both dimensions (operations and problem solving), whereas the two groups performed equally on the operation dimension on the complex and real-world problem task. In contrast, the MD-only group outperformed the MD–RD group on the problem-solving dimension on the two more difficult problem-solving tasks. Fuchs and Fuchs posited that these findings were due to the fact that the complex story problem and real-world problem tasks involved more difficult operational demands than the arithmetic story problem task. The latter task required only number fact skills, whereas the two other tasks required algorithm and application skills as well as number fact skills. Thus, the advantage of the MD-only children over the MD–RD children concerning operational ability was restricted to simple number fact operation but did not involve more complex mathematical operations. The MD-only children, in contrast, appeared to have overall better developed problem comprehension abilities (establishing a problem representation and a solution plan; Kintsch & Greeno, 1985; Mayer & Hegarty, 1996) than children with MD–RD (Fuchs & Fuchs, 2002; see also Hanich et al., 2001; Jordan & Hanich, 2000; Jordan & Montani, 1997).

In sum, previous research has provided consistent evidence that arithmetic and mathematic problem solving is a mathematic domain that imposes severe difficulties for children with MD, and especially for children with comorbid RD. However, more research is required that focuses on complex mathematic word problem-solving ability in children with MD and MD–RD. The more severe comprehension and problem-solving difficulties in children with MD–RD are most likely, to some extent, a result of their reading deficit, which might prevent the children from having full access to the problem text. It is also possible that the reading deficit in children with MD–RD reflects a general weakness in language comprehension. As such, it would constitute a major obstacle when the child must comprehend word problems even if the problem is orally presented to the child.

## Place Value and Written Multidigit Calculation

Only four studies have included measures tapping children's understanding of place value and skill in written multidigit calculation when studying children with MD. This is surprising considering that place value is a basic mathematic concept, and written multidigit calculation can be considered a natural second step (after basic number fact skills) in children's learning of basic mathematic skills. In all four available studies children with MD–RD obtained significantly lower scores on multidigit calculation tasks than normally achieving children (Hanich et al., 2001; Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003; Russell & Ginsburg, 1984). Furthermore, Jordan and Hanich and Hanich et al. found that children with RD only performed better than MD–RD children. Jordan and colleagues also found that second and third graders with MD–RD had a poorer understanding of place value compared to normally achieving children (Hanich et al., 2001; Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003). In Russell and Ginsburg's study of fourth graders, children with MD–RD displayed as good an understanding of place value as the age-matched controls. In relation to children with MD only, two studies have demonstrated that they have a weakness in written multidigit calculation and poorer understanding of place value in comparison to age-matched controls (Hanich et al., 2001; Jordan, Hanich, & Kaplan, 2003). Jordan and Hanich, in contrast, found that children with MD only performed on a par with normally achieving children but better than MD–RD children on written multidigit calculation. An error analysis indicated that the performance pattern of MD–RD children was qualitatively different from that of children with MD only. The MD–RD children's errors indicated that they have poor reasoning or judgment skills, whereas the MD-only children's errors consisted of calculation bugs (e.g., minor miscalculations, wrong operations, etc.) similar to those made by normally achieving children.

In sum, due to the limited research no firm conclusions can be drawn with regard to these aspects of mathematic cognition and MD. The only conclusion that can be drawn with some confidence is that children with MD have problems with multidigit calculation. The concept of place value might be a problem for second and third graders with MD–RD but not fourth graders. Previous studies have also given some indication that poor understanding of place value might have a negative effect on the child's ability to perform written multidigit calculations (Jordan, Hanich, & Kaplan, 2003).

## Calculation Principles

Developing an understanding of the relationships within and between arithmetic operations (i.e., calculation principles) is a prerequisite for accurate and efficient multidigit calculation and mathematic word problem solving (Geary, 1994; Jordan, Hanich, & Uberty, 2003). Studies performed by Jordan and colleagues (Hanich et al., 2001; Jordan, Hanich, & Kaplan, 2003) have indicated that both groups of children with MD have a weakness regarding this aspect of mathematics in Grades 2 and 3. Jordan, Hanich, and Kaplan (2003) also found that third graders with MD–RD have a poorer understanding of calculation principles compared to children with MD only. Russell and Ginsburg (1984), however, did not find any evidence that fourth graders with MD–RD have a vague understanding of calculation principles. So,

the empirical picture concerning the understanding of calculation principles in children with MD is unclear due to there being few available studies. The present study, therefore, sought to examine this area of mathematics in children with MD.

### Approximate Arithmetic

Findings reported by Hanich et al. (2001) and Jordan, Hanich, and Kaplan (2003) have suggested that approximate arithmetic (i.e., the ability to quickly provide an estimated result of an arithmetic problem) is a core deficit for children with MD only and MD-RD. Brain imaging data suggest that when performing this type of task, the individual employs a mental spatial number line that draws upon visuospatial circuits of the dorsal parietal pathway of the brain (Dehaene, Spelke, Pinel, Stanescu, & Tsivkin, 1999; see also Dehaene & Cohen, 1991). Thus, approximate arithmetic seems to rely on visuospatial abilities and seems to be independent of language (Dehaene et al., 1999; Hanich et al., 2001; Jordan, Hanich, & Kaplan, 2003). The empirical picture regarding approximate arithmetic is, however, far from clear as only two studies have provided evidence that children with MD have a weakness within this domain. To further complicate the picture, Russell and Ginsburg (1984) found that children in Grade 4 with MD-RD did not perform worse than normally achieving children. Hence, more research is required to obtain a clearer view of the relationship between MD and approximate arithmetic.

### Time Telling

Time telling is a complex and important cognitive skill that is required on a daily basis (Bock, Irwin, Davidson, & Levelt, 2003; Friedman & Laycock, 1989). Available studies have shown that the ability to tell time from analog clocks develops in a particular order. Most children are able to tell whole-hour times by age 6, half-hour times by age 7, quarter-hour times by age 9, and 5- and 1-min times by ages 8 to 10 (Case, Sandieson, & Dennis, 1986; Friedman & Laycock, 1989; Siegler & McGilly, 1989; Vakali, 1991). According to Friedman and Laycock's study, the ability to tell the time of digital clocks develops much earlier than that of analog clocks. The researchers found that all second graders (mean age = 7.70 years) were able to correctly identify whole-hour times, half-hour times, and 1-min times for digital clocks. The similar performance level for analog clocks was not reached until age 10.

Previous research has also demonstrated that children employ a mixture of retrieval and procedural strategies when they tell time, and that older children rely more on retrieval strategies than younger children (Case et al., 1986; Friedman & Laycock, 1989; Siegler & McGilly, 1989; Vakali, 1991). According to Friedman and Laycock (1989), time telling

includes attending to the numerals to which the hour hand points or, if necessary, has passed most recently to get the hour value, determining the minute value by counting clockwise by 5s from the top of the clock face until the 5-min mark pointed to or immediately preceding the minute hand pointing is reached, and, if necessary, counting the remaining hash marks by 1s. (p. 357)

Furthermore, time-telling problems such as whole-hour analog times and half-hour analog times seem to be solved by retrieving

a preexisting answer from long-term memory. Thus, it is assumed that the child develops memory representations regarding the associations between particular configurations and the time names (Friedman & Laycock, 1989; Siegler & McGilly, 1989). Results reported by Friedman and Laycock have indicated that telling the time of digital clocks seems to involve quite different processes compared to that of analog clocks. Telling the time of digital clocks (e.g., 13:25) is quite similar to decoding regular one- and two-digit numbers (9 or 22), as the hour and minute values are presented as numbers. Thus, time telling of digital clocks is basically a question of retrieving number names. However, the child needs to know that the colon is used to separate the hour value and the minute value, that X:00 is read as "o'clock," and that a zero in the tens place to the right of the colon is read as "oh." Because telling time is a skill that in many respects resembles basic arithmetic (counting procedures and fact retrieval), it would be interesting to examine the time-telling skills in children with MD only and MD-RD, something that was not done in previous studies.

### Mathematic Skill in Children With RD Only

MD in children often coexist with RD (Ackerman & Dykman, 1995; Gathercole, Alloway, Willis, & Adams, 2006; Geary, 1993; Lewis, Hitch, & Walker, 1994). Reading ability also seems to have an impact on children's mathematical ability, as children with MD-RD perform worse than children with MD only within specific areas of mathematics (e.g., story problems and exact calculation of arithmetic combinations), whereas children with MD-RD display similar levels of reading ability as children with RD only. As a matter of fact, Jordan, Kaplan, and Hanich (2002) presented evidence that suggests that children identified with RD only in early grades (second grade) are at risk for developing MD in higher grades (third grade). Consistent with the assumption that the RD in children with RD only may have a negative impact on these children's mathematic skills, Geary et al. (2000) and Hanich et al. (2001) observed that children with RD only achieved significantly worse results than age-matched controls on a forced addition fact retrieval task. Jordan and colleagues (Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003) demonstrated that second and third graders with RD only may have a vague understanding of the concept of place value. Furthermore, Jordan, Hanich, and Kaplan (2003) found that third graders with RD only obtained lower scores on written multidigit calculation and a simple story problem task. Thus, in line with the findings of Jordan et al. (2002), it is possible that children with RD only may encounter difficulties in later elementary school within certain areas of mathematics (e.g., complex word problem solving) that are mediated via language (i.e., reading). It should, however, be pointed out that previous studies on children with RD only have shown that these children perform on a par with normally achieving children on most aspects of mathematic cognition (Geary et al., 1999; Jordan & Hanich, 2000). Thus, it remains to be seen whether children with RD only have weaknesses in specific domains of mathematics.

To summarize, research has shown that children with MD or MD-RD have weaknesses in many areas of mathematics, but it is important to regard children with MD only and children with MD-RD as separate subgroups of children with MD. Overall, children with MD-RD display more severe difficulties than children with MD only. More specifically, children with MD-RD have

greater deficiencies with arithmetic problem solving and exact calculation of arithmetic combinations, whereas their problems in other areas of mathematic cognition (such as forced retrieval of arithmetic facts, approximate arithmetic, place value, calculation principles, and written calculation) are equal to those of children with MD only. So, children with MD only show an advantage over children with MD–RD in areas that can be mediated by language (e.g., story problems and exact calculation of arithmetic combinations) but not in areas that appear to depend on numerical magnitude and automaticity (e.g., approximate arithmetic, arithmetic fact retrieval). The negative influence RD have on the mathematical ability of children with MD–RD might also be present for children with RD only; that is, these children may encounter difficulties in later elementary school with areas of mathematics that are mediated via language (i.e., reading).

### The Present Study

The present study was an attempt to extend previous findings regarding mathematic competencies of children with MD only, MD–RD, and RD only. To reach this goal, relatively large samples of children with MD only, MD–RD, and also RD only were assessed on multiple areas of mathematic cognition and compared to children with normal achievement. Similar to studies by Jordan and colleagues (Hanich et al., 2001; Jordan, Hanich, & Kaplan, 2003; see also Russell & Ginsburg, 1984), measures of addition and subtraction fact retrieval, written multidigit calculation, calculation principles, place value, and approximate arithmetic were employed. In addition to these measures, a multiplication fact retrieval task was included in the study. In contrast to the majority of previous studies, the present study included one-step mathematic word problems that required multidigit calculation as well as number fact skills and complex mathematic word problems that required multistep solutions and multidigit calculation (cf. Fuchs & Fuchs, 2002). As time telling is an important skill that is required on a daily basis, the present study assessed this aspect of mathematics in the four subgroups of children (including normally achieving children). Screening tests of mathematics and reading were included to establish that the groups of children classified as having MD and/or RD indeed performed significantly poorer than the group of normally achieving children.

### Supporting Cognitive Functions and Measures of IQ

A large body of research has demonstrated that many areas of mathematic cognition in children are supported by basic cognitive functions such as working-memory capacity, general processing speed, and executive functions (Andersson, in press; Bull & Scerif, 2001; Geary, 2004; Passolunghi & Pazzaglia, 2004; Swanson, 1994, 2006; Swanson & Beebe-Frankenberger, 2004). In addition, these basic cognitive functions have been found to be poorer in children with MD and MD–RD compared to age-matched normally achieving children (Andersson & Lyxell, 2007; Bull & Johnston, 1997; Hitch & McAuley, 1991; McLean & Hitch, 1999; Passolunghi & Siegel, 2004; Siegel & Ryan, 1989; Swanson, 1994; Swanson & Beebe-Frankenberger, 2004). Hence, in order to examine and, if necessary, control for possible group differences in basic cognitive functioning, three tasks tapping these functions were included in the study (visual-matrix span, number matching,

trail making; Andersson & Lyxell, 2007; Bull & Johnston, 1997). Raven's progressive matrices (Raven, 1976) and a verbal ability task (Järpsten & Taube, 1997) were also employed in order to examine group differences in mathematics beyond the influence of verbal and nonverbal IQ.

In sum, by using larger samples and more extensive measurement than previous research, the present study has the potential to contribute to the research literature on MD in children. The present article examined data from the first-year assessment of a 3-year longitudinal study on (a) the development of mathematic skills in children with MD only, RD only, and MD–RD; and (b) how development in mathematics is connected to reading development and vice versa. However, the reading-related tasks included in this project are not presented, because they do not provide any additional information to the present article that focuses on different areas of mathematic cognition. The reading tasks will hopefully provide important information when data have been collected for all 3 years.

### Predictions and Specific Research Questions

The following predictions and specific research questions were examined in relation to the different areas of mathematic cognition.

1. It was predicted that children with MD only and MD–RD would show weaknesses in all of the examined areas of mathematic cognition. That is, they would perform significantly poorer than the normally achieving children on all mathematic tasks. It was, however, expected that both groups of children with MD would display more severe problems with arithmetic facts retrieval, mathematic word problem solving, and written multidigit arithmetic calculation compared to areas such as place value and calculation principles (cf. Hanich et al., 2001; Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003; Russell & Ginsburg, 1984).

2. The two groups with MD were expected to perform equally on forced arithmetic fact retrieval, approximate arithmetic, place value, calculation principles, and written calculation. However, as mathematic word problem solving is mediated by language, the MD-only children were expected to have an advantage over the MD–RD children in word problem solving due to their better developed reading (language) skills and also due to their better problem comprehension abilities (cf. Fuchs & Fuchs, 2002; Hanich et al., 2001; Jordan & Hanich, 2000; Jordan & Montani, 1997).

3. A specific interest of the present study was to examine whether weaknesses in arithmetic fact retrieval can account for the expected low performance of the two MD groups on written calculation. That is, will children with MD only and MD–RD still perform lower than the controls on written multidigit calculation when expected group differences in arithmetic fact retrieval are controlled for?

4. As the understanding of calculation principles and skills in written calculation is important for accurate and efficient problem solving, the present study sought to examine whether the poor performance of the MD-only group and the MD–RD group on mathematic word problem solving is due to the previously mentioned mathematic skill. That is, will children with MD only and MD–RD still perform lower than the controls on mathematic word

problem solving when expected group differences in written multidigit calculation and understanding of calculation principles are controlled for?

5. A specific interest of the present study was to examine whether children with RD only have weaknesses in specific domains of mathematics that are mediated by language (i.e., word problem solving, arithmetic facts, written multidigit calculation; Dehaene, 1992; Geary, 1993, 2004; Kulak, 1993).

6. As telling time is a skill that in many respects resembles basic arithmetic (counting procedures and fact retrieval), the present study also sought to address the question whether children with MD only or MD–RD have difficulties with this aspect of mathematics.

## Method

### Participants

A total of 182 third ( $n = 88$ ) and fourth graders ( $n = 94$ ) attending 28 schools in the southern parts of Sweden participated in this study. The children were recruited by means of a letter of consent that the children took home to the parents from school. Fortunately, very few of the children with MD only, RD only, and MD–RD who were asked to participate in the study declined to participate, and because the children were drawn from many schools (i.e., 28) one might assume that the present children provide representative samples of the populations of children with MD only, RD only, and MD–RD. The total sample had a mean age of 125 months ( $SD = 7.00$ ). All children were fluent speakers of Swedish, had normal or corrected-to-normal visual acuity, and had no hearing loss. Children diagnosed with neurological disturbances (e.g., attention-deficit/hyperactivity disorder) were excluded from the study.

The criterion for being classified into the three disability groups was that the child received special instruction either in mathematics (MD only), reading (RD only), or both mathematics and reading (MD–RD) at the time of the study. An additional selection criterion was that the child's score on Raven's Standard Progressive Matrices test and the verbal ability test was at most 1.50  $SD$  below the group mean of the normally achieving children of the same age. The decision to provide special instruction to the children with MD only, RD only, or MD–RD in the present study was based on several sources of information. Potential learning problems in relation to mathematics and reading were first observed by the classroom teachers. The teachers' observation of the children's poor classroom performance in mathematics and/or reading was then supplemented by diagnostic testing, followed by an evaluation by special educators. The information obtained by the classroom teachers, the diagnostic tests, and the special educators revealed that the level of skill in mathematics and/or reading of the present children was considerably below that expected in Grades 3 or 4. It was therefore decided that the children should receive special instruction in mathematics, reading, or both.

### General Testing Procedure

This research was part of an ongoing longitudinal study of mathematic development in children with learning difficulties and its relation to reading development. However, four reading-related

tasks included in this project are not examined in this article (see the discussion in the section *Supporting Cognitive Functions and Measures of IQ*).

Each child undertook a total of 19 tests (including the screening tasks and IQ measures) that were administered in two separate sessions: a group test session and an individual test session. Approximately 1 to 4 weeks after the group test, the individual test session was performed. The test order was the same for all children. All instructions regarding the tasks, in both test sessions, were presented orally. Ten female experimenters performed all testing.

*Group test session.* Nine tests were administered during the group test session, but only six of the tests are reported in the present article. The tasks, in order of presentation, were the screening test of mathematics, the screening test of reading, Raven's Standard Progressive Matrices test (Raven, 1976; sets B, C, and D), the place value test, the word ability test (Järpsten & Taube, 1997), and multidigit written calculation. The group test session took approximately 120 min, divided into three 40-min sessions with 10- to 15-min breaks in between. That is, the session was the length of a regular lesson in the Swedish elementary school.

*Individual test session.* The relevant tasks in this session, in order of presentation, were as follows: arithmetic fact retrieval, visual-matrix span, calculation principles, telling time, approximate arithmetic, number matching, one-step mathematic problem solving, multistep word problem solving, and trail making. The individual test session took approximately 120 min, divided into three 40-min sessions with 10- to 15-min breaks in between.

### Screening Tests and Tests of Verbal and Nonverbal IQ

Screening tests of mathematics and reading, the word ability test (Järpsten & Taube, 1997), and Raven's Standard Progressive Matrices test (Raven, 1976; sets B, C, and D) were administered in the group test session to obtain measures of mathematic ability, reading ability, and nonverbal and verbal IQ. The mathematic and reading screening tasks were included to establish that the groups of children classified as having MD and/or RD indeed performed significantly poorer than the group of normally achieving children.

*Mathematic screening test.* The screening test was a paper-and-pencil test and consisted of three subtests. All three subtests were designed so that the test items became successively more difficult. The children were instructed that they could solve the problems in any way they wanted, and that they should not struggle and spend too much time on a single problem but instead try the next problem. Paper and pencil were allowed during performance of the task. The number of correctly solved problems was used as dependent measure. The maximum score was 32.

In the first subtest, the child was asked to solve five addition problems and five subtraction problems ( $568 + 421$ ;  $658 - 437$ ;  $56 + 47$ ;  $65 - 29$ ;  $545 + 96$ ;  $384 + 278$ ;  $824 - 488$ ;  $4203 + 5825$ ;  $8010 - 914$ ;  $11305 - 5786$ ) during 8 min. The problems were presented horizontally, because this is the primary form of presentation when starting to teach children multidigit arithmetic in Sweden. The children responded in Arabic form (e.g., 103). Half the problems involved regrouping (i.e., carrying or borrowing).

The second subtest consisted of 12 arithmetic equations presented horizontally ( $61 + \_\_\_ = 73$ ;  $\_\_\_ \times 4 = 16$ ;  $\_\_\_ \times 5 = 40$ ;  $\_\_\_ + 25 = 500$ ;  $1000 - \_\_\_ = 550$ ;  $\_\_\_ - 8 = 6$ ;  $8 \times \_\_\_$

= 24; \_\_\_\_ - 50 = 50; \_\_\_\_ - 445 = 55; 13 = 6 + \_\_\_\_; 136 = \_\_\_\_ + 27; 360 = \_\_\_\_ - 610). The task was to fill in the right number so that the equation was correct. The children were allowed 7 min to complete that task. The subtest was preceded by two practice trials before the actual testing started to ensure that the children understood the task.

In the third subtest, the child was presented with an answer and two to four numbers that had to be combined with one to three arithmetic operations (addition, subtraction, multiplication) in order to obtain the predetermined answer. For example, if the answer was 12 and the three numbers were 5, 8, 9, a correct combination would be 9 + 8 - 5. Ten problems were included in this subtest (27, 113 = 140; 11, 26 = 15; 5, 8, 9 = 12; 10, 50, 90 = 30; 11, 19, 25 = 33; 4, 16, 4 = 0; 25, 19, 11 = 5; 4, 2, 5, 9 = 9; 2, 5, 30, 60 = 100; 1, 3, 8, 25 = 0). The children were allowed 5 min to complete that task. The subtest was preceded by three practice trials before the actual testing started. Cronbach's alpha coefficients for the first, second, and third subtests have been established at .82 (*n* = 110), .81 (*n* = 186), and .74 (*n* = 148), respectively, in samples of children aged between 9 and 11 years. The reliability estimate for the third subtest was calculated on 6 out of 10 items to obtain a larger sample of children. The intercorrelations among the three subtests calculated on the sample of 186 children were significant and ranged from .54 to .65 (*p* < .01).

*Reading screening test (Malmquist, 1969).* The child had to read a short fable story (600 words in length) about a turtle and a water buffalo stealing bananas from a gardener. In the text, 20 sentences were incomplete (i.e., one word was missing and replaced by three single words within parentheses). The child was asked to read the story as quickly and accurately as possible and to select one of the three words to complete the sentence in an appropriate way. The child was allowed 4 min to work with the test. The total number of correctly completed sentences was used as dependent measure. The maximum score was 20. The reported split-half reliability after Spearman-Brown correction for this task is .94 (see Malmquist, 1977).

*Word knowledge test (Järpsten & Taube, 1997).* In this multiple-choice response test, the child had to indicate the meaning of a target word by choosing one of four options (e.g., "The word pal means the same as (a) girl, (b) boy, (c) child, (d) buddy"). Each child received a test booklet that included 24 items, and the child responded by checking one of the four options. As many of the children had poor reading skills, the experimenter read each prob-

lem and all response options to the children while they followed along in the booklet. Prior to the actual testing, two practice trials were completed. Järpsten and Taube reported a Cronbach's alpha coefficient for the word knowledge test of .87 calculated on a sample of 665 children aged between 10 and 11 years. The maximum score was 24.

*Raven's Standard Progressive Matrices test.* The test consists of a series of visual pattern designs with a piece missing. The task is to select the correct piece to complete the designs from a number of options (six to eight) displayed beneath the design. The complete test includes five sets of designs (A, B, C, D, E), and each set consists of 12 items (Raven, 1976). In the present study only sets B, C, and D were used; thus, the maximum score was 36. For set B six response options were displayed, and for sets C and D eight response options. Each child received a test booklet that included 36 test items and 2 practice items. The children responded by checking one of the six to eight options on a separate answer sheet. After the two practice items had been completed, the children completed their booklets at their own pace. The specific instructions and administration procedures followed those specified in the test manual, and the reported Cronbach's alpha coefficients for the test usually lie in the range between .90 and .97 (see Raven, Court, & Raven, 1996).

More detailed information regarding mean age; gender; number of participants; and results on Raven's Standard Progressive Matrices test, the word ability test, and screening tasks for mathematics and reading for each achievement group are displayed in Table 1.

One-way analyses of variance (ANOVAs) were computed to compare the groups on measures of nonverbal (Raven) and verbal IQ (word ability test), mathematics, and reading. Because of the number of comparisons, a significance level of *p* < .01 was employed for all statistical procedures in the study.

The results of the ANOVAs and subsequent post hoc tests (Tukey-Kramer) revealed that both groups of children with mathematic difficulties (MD only and MD-RD) performed significantly lower on the mathematic screening task, *F*(3, 178) = 20.23, *p* < .01, and that the RD-only children and the MD-RD children performed significantly lower on the reading task, *F*(3, 178) = 10.71, *p* < .01, compared to the controls. However, no significant group differences emerged on Raven's Standard Progressive Matrices and the verbal ability test (all *ps* > .01).

Table 1  
*Descriptive Information for Participants by Achievement Group*

Characteristic	MD only		MD-RD		RD only		Controls	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Mean age (in months)	125	5.97	125	7.10	128	7.41	125	7.26
Raven's Standard Progressive Matrices (raw score)	20.66	5.02	21.42	4.20	22.63	4.87	21.62	6.52
Word knowledge task (raw score)	13.78	2.93	14.00	2.68	13.63	2.99	14.28	3.16
Mathematic screening task	9.24	4.16	9.90	4.45	13.97	6.06	15.89	5.44
Reading screening task	10.24	3.42	6.82	3.12	7.80	3.18	12.13	3.46
<i>N</i> (number of boys)	41 (10)		50 (21)		30 (23)		61 (33)	

*Note.* MD only = children with mathematical difficulties only (i.e., normal reading ability); MD-RD = children with both mathematical and reading difficulties; RD only = children with reading difficulties only (i.e., normal mathematical ability).

### Experimental Tasks and Procedure

**Arithmetic fact retrieval.** The task assessed automatic retrieval of arithmetic facts. The test material consisted of 12 addition combinations ( $5 + 4$ ;  $8 + 5$ ;  $7 + 4$ ;  $9 + 5$ ;  $3 + 8$ ;  $7 + 9$ ;  $4 + 6$ ;  $3 + 9$ ;  $7 + 8$ ;  $8 + 4$ ;  $3 + 6$ ;  $6 + 5$ ), 12 subtraction combinations ( $9 - 4$ ;  $7 - 4$ ;  $9 - 5$ ;  $7 - 5$ ;  $8 - 4$ ;  $9 - 7$ ;  $6 - 3$ ;  $8 - 3$ ;  $6 - 2$ ;  $9 - 3$ ;  $9 - 6$ ;  $7 - 3$ ), and 12 multiplication combinations ( $4 \times 5$ ;  $2 \times 7$ ;  $9 \times 4$ ;  $9 \times 10$ ;  $7 \times 5$ ;  $6 \times 3$ ;  $9 \times 2$ ;  $7 \times 3$ ;  $6 \times 6$ ;  $4 \times 6$ ;  $3 \times 4$ ;  $5 \times 6$ ). The task was administered on three separate sheets of paper, one for each operation. On the three sheets the 12 number combinations were presented in a column. All children started with the addition condition, followed by the subtraction condition, and the multiplication condition. The child was instructed to provide an answer right away and was encouraged to guess if the answer was not available right away. The experimenter used a stopwatch to measure the total time it took to provide answers to the 12 number combinations and to register whether the response time was longer than 3 s for each individual problem. During performance the experimenter also continually checked the child's answers and registered each error. The total number of correctly solved problems for each condition and all three conditions together with response times within 3 s were used as dependent measures (cf. Russell & Ginsburg, 1984). In addition, the overall error rate for responses within and above 3 s was used as a dependent measure. The Cronbach's alpha coefficients for the addition, subtraction, and multiplication fact retrieval tasks calculated on the present sample were .85, .87, and .86, respectively.

**Written multidigit arithmetic calculation.** This was a paper-and-pencil test and consisted of 12 vertically presented multidigit calculation problems. The child was asked to solve five addition problems and seven subtraction problems ( $258 + 341$ ;  $45 + 67$ ;  $78 - 56$ ;  $647 - 566$ ;  $459 - 279$ ;  $545 - 378$ ;  $1295 + 5437$ ;  $3874 + 8566$ ;  $26856 + 14249$ ;  $9566 - 978$ ;  $2023 - 1455$ ;  $12405 - 7748$ ). The task was designed so that the test items became successively more difficult. All but two problems ( $258 + 341$ ;  $78 - 56$ ) involved regrouping. The child was allowed 10 min to complete the task. The maximum score was 12, and the Cronbach's alpha coefficient for the task was .88, calculated on a sample of 171 children aged 9 to 11 years.

**One-step mathematic word problems.** The child was asked to solve 14 written mathematic word problems by means of paper and pencil during 15 min (e.g., "John had 65 crowns left when he had bought a book for 36 crowns. How much did he have to start with?"). In order to impose as little linguistic demand as possible, the problems were one to three sentences long and did not include any irrelevant information. All but two problems included multidigit calculation. The task was designed so that the test items became successively more difficult. The experimenter and the child sat next to each other during the administration of the task. The experimenter read the individual problems while the child followed along on the paper. If requested by the child the experimenter reread the problem. This test administration procedure was chosen because of the poor reading skills of many of the children (i.e., MD-RD and RD only), although a redundancy effect can emerge as a result of having the child listen and read the same material simultaneously (Kalyuga, Chandler, & Sweller, 2004; Sweller, 2005). The negative impact of poor reading skills on task performance was, however, considered to be worse than the neg-

ative impact of the redundancy effect (cf. Fuchs & Fuchs, 2002; Swanson & Beebe-Frankenberger, 2004). The presentation order of the problems was the same for all children, and the children responded in writing. The maximum score was 14. The alpha coefficient for the task was .82, calculated on a sample of 147 children aged 9 to 11 years. The reliability estimate was based on the first 12 items out of 14 items to obtain a larger sample of children. None of the children in the present sample attempted to solve Items 13 and 14.

**Complex multistep mathematic word problems.** The complexity of mathematic word problems can be enhanced in a number of ways, for example by including irrelevant information and/or using indirect language (Fuchs & Fuchs, 2002; Parmar et al., 1996; Russell & Ginsburg, 1984). Another way to increase the complexity is to use problems that require multiple solution steps (Fuchs & Fuchs, 2002; Parmar et al., 1996). The present study adopted this latter approach for two reasons. First, the primary interest was to examine the children's mathematic problem-solving abilities, not their linguistic abilities; thus, using word problems that were mathematically complex appeared to be the adequate approach. Second, because two groups of children (i.e., MD-RD, RD only) had RD, it was quite possible that their reading problems might mask their "true" mathematic problem-solving abilities (the operation and problem-solving dimensions; Fuchs & Fuchs, 2002) if the problems imposed high linguistic demands by including irrelevant information.

The child was asked to solve seven written mathematic word problems that required at least two calculation steps in order to reach a correct solution (e.g., "Mark weighs 38 kg. His dad weighs 35 kg more. How much do they weigh together?"). The problems were two to four sentences long and did not include any irrelevant information. Thus, the linguistic demand was low as in the one-step problems. All problems included multidigit calculation. The same administration procedure as for the one-step mathematic word problems was used. Seven was the maximum score. The alpha coefficient for the task was .72, calculated on a sample of 166 children aged 9 to 11 years.

**Place value.** The child's understanding of the base-10 number system and place value (Jordan & Hanich, 2000) was tapped by a paper-and-pencil test that consisted of three parts. In Part 1, the child was presented with four 3-digit numbers and one 4-digit number and was asked to indicate, in writing, the value of a particular digit (e.g., "What is the value of the digit 9 in 349?" "What is the value of the digit 4 in 479?" "What is the value of the digit 8 in 986?" "What is the value of the digit 6 in 6821?" "What is the value of the digit 5 in 257?"). In Part 2, the child was asked to answer, in writing, seven questions regarding which number consists of a certain number of thousands, hundreds, tens, and ones. The seven questions were presented in the following format: Indicate in writing the number that consists of 3 hundreds, 6 tens, and 3 ones (i.e., 363). In Part 3, the child was presented with five pairs of written numbers (799999–811111; 522222–288888; 9444444–4999999; 0.299999–0.611111; 0.099999–0.100000) and was required to indicate the larger number of each pair by making a circle around the larger number (see Russell & Ginsburg, 1984). The second number in the pair was positioned beneath the first number in the pair. The maximum score was 17, and Cronbach's alpha calculated on the present sample was .78.

*Calculation principles task.* This task assessed the child's understanding of three calculation principles: the commutativity principle (i.e., that the order of addends does not affect the sum), the inversion principle (i.e., that subtraction is the inversion of addition and vice versa), and the double-plus-one principle. The task was a version of the task developed by Russell and Ginsburg (1984; see also Baroody & Wilkins, 1999) and included a total of 10 problems. Three problems assessed the commutativity principle ( $26 + 32 = 58$ , so what is  $32 + 26 = ?$ ;  $15 + 19 = 34$ , so what is  $19 + 15 = ?$ ;  $48 + 21 = 69$ , so what is  $21 + 48 = ?$ ), four problems assessed the inversion principle ( $23 + 14 = 37$ , so what is  $37 - 14 = ?$ ;  $27 + 69 = 96$ , so what is  $96 - 69 = ?$ ;  $59 - 15 = 44$ , so what is  $44 + 15 = ?$ ;  $79 - 12 = 67$ , so what is  $67 + 12 = ?$ ), and three problems assessed the double-plus-one principle ( $37 + 37 = 74$ , so what is  $37 + 38 = ?$ ;  $42 + 42 = 84$ , so what is  $42 + 43 = ?$ ;  $68 + 68 = 136$ , so what is  $68 + 69 = ?$ ). The task was designed so that the answer to the first number combination (e.g.,  $26 + 32 = 58$ ) could be used to solve the second combination ( $32 + 26 = ?$ ). The 10 problems were presented in a vertical format on three separate sheets of paper, one for each principle; the experimenter read and showed each problem to the child. To prevent the child from calculating, a maximum response time of 5 s was employed (Hanich et al., 2001). If the child did not respond within the 5-s interval, the answer was considered incorrect. The maximum score was 10, and Cronbach's alpha calculated on the present sample was .78.

*Approximate arithmetic.* This task was adapted from Dehaene et al. (1999). The test material consisted of seven addition and seven subtraction combinations, and each item was accompanied by two proposed answers (e.g.,  $72$  or  $60$ ,  $52 + 17 = ?$ ;  $47$  or  $36$ ,  $57 - 23 = ?$ ). The task was to choose the answer that was closest to the correct answer. In contrast to the procedure used by Dehaene et al., the two proposed answers were presented first, followed by the arithmetic combination (e.g., first  $72 - 60$ , and then  $52 + 17 = ?$ ). The 14 combinations were presented in a vertical format on two separate sheets of paper, one for addition and one for subtraction; all children started with the addition condition. The experimenter displayed one combination at a time to the child. The child was instructed to provide an answer right away and not to calculate an exact answer to the combination. To prevent the child from calculating, a maximum response time of 5 s was employed (Hanich et al., 2001). A stopwatch was used to register whether the response time was longer than 5 s for each individual problem. If the child did not respond within the 5-s interval the answer was considered incorrect and the child was instructed to respond quicker. Two practice trials were presented to the child before the actual test phase started to ensure that the child understood the task. The maximum score was 14, and Cronbach's alpha calculated on the present sample was .80.

*Telling time.* This task was developed by the author and consisted of four analog clocks (08:30; 10:15; 15:40; 21:55) and four digital clocks (07:35; 21:00; 13:15; 01:45) presented on a paper. The analog clocks were also supplemented with information regarding whether it was the morning (a.m.) or the evening (p.m.). When telling the time of the four analog clocks, the child had to express the time in words (e.g., quarter past ten) and in digital form (e.g., 10:15). Thus, the child could receive 0, 1, or 2 points for each analog clock. When telling the time of the four digital clocks, the child had to express the time in words and also state whether it was

the morning, forenoon, afternoon, evening, or during the night. The child could receive 0, 1, or 2 points for each one of the eight clocks. Thus, the maximum score was 16, and the child responded in writing. Cronbach's alpha coefficient for the task was .88, calculated on the present sample.

*Number-matching task.* This task was used to measure general processing speed. Each child was given a sheet of paper with 30 rows of digits. Each row consisted of seven digits, with 2 digits in each row being identical. The child's task was to cross out the two identical digits in each row as fast and accurately as possible. A practice trial of seven rows was performed before the actual task started. Performance was measured by the time taken to complete all 30 rows. Test-retest reliability of .79 was established for this task based on a sample of 156 children aged 9 to 13 years.

*Visual-matrix span task.* This task was a version of Swanson's (1992) visual working-memory task. The child was presented with a number of dots in a matrix. The task was to remember the location of the dots in the matrix. A total of 32 matrices constituted the test material. The matrices were made up of different numbers of squares. Each square was 2 cm and was drawn on a white background. The dots were black, with a diameter of 1 cm. One matrix at a time was displayed on a sheet of paper for 5 s. Then the matrix was removed, and the child was asked a process question: "Were there any dots in the first column?" After answering the process question, the child was required to draw dots in the correct squares on an identical matrix. The first matrix had nine squares ( $3 \times 3$ ) and included two dots. The matrices on the next span size had nine squares ( $3 \times 3$ ) and three dots. The third span size had 12 squares and included three dots. The complexity of the matrices increased for each new span size either by increasing the size of the matrix or increasing the number of dots. The complexity ranged from a matrix of 9 squares and two dots to a matrix of 36 squares and eight dots. Two different matrices were presented for each span size. Testing stopped when the child failed to repeat both trials at any particular span length. Thus, testing proceeded as long as the child succeeded in reproducing one of the two trials of the same span length. Visual-matrix span was measured as the most complex matrix remembered correctly, plus 0.5 points if the participant managed to replicate correctly both trials in the same span length. Andersson (in press) reported a test-retest reliability of .60 for this task.

*Trail-making task.* This classic paper-and-pencil test was used to assess the ability to switch between operations or retrieval strategies, which is assumed to be an important executive function (Baddeley, 1996; Lee, Cheung, Chan, & Chan, 2000; McLean & Hitch, 1999; Miyake et al., 2000). The task included two different test conditions, A and B. In the A condition, the material consisted of 25 encircled numbers on a sheet of paper. The task was to connect the 25 circles in numerical order as fast and accurately as possible. Each child was presented with a practice trial consisting of eight circles (1-2-3-4-5-6-7-8) and was instructed to solve it before the actual trail-making tasks commenced. In the B condition, half the circles had a number in the center (1-13) and half had a letter (A-L). The children were asked to start at number 1 and make a trail with a pencil so that each number alternated with its corresponding letter (i.e., 1-A-2-B-3-C . . . 12-L-13). Each child was presented with a practice trial consisting of eight circles (1-A-2-B-3-C-4-D) and was instructed to solve it before the actual trail-making tasks commenced. The difference in solution

time for the B condition and A condition (i.e.,  $B - A$ ) was used as dependent measure. Reported reliabilities for this task lie between .60 and .90 (Lezak, 1995).

## Results

Descriptive statistics for the overall accuracy scores for the eight mathematic tasks and the three cognitive tasks for each achievement group, and correlations among the tasks, are displayed in Tables 2 and 3.

### Overall Performance on the Mathematic and Cognitive Tasks

As a first step to test the hypotheses of the present study, ANOVAs and effect sizes ( $\eta^2$ ) were calculated for the eight mathematic tasks (overall scores) and the three cognitive tasks. According to Cohen (1988), an effect size of .09 or less is considered to be small, whereas an effect size between .10 to .24 is of medium size. An effect size of .25 or larger is considered to represent a large effect. The statistics from the first 12 ANOVAs are presented in Table 4.

**Arithmetic fact retrieval.** Two ANOVAs were calculated on the arithmetic fact retrieval task, one for overall accuracy for responses within 3 s and one for overall error rate for responses within and above 3 s. A significant and large group effect emerged for overall accuracy, and the Tukey-Kramer post hoc test revealed that both groups with MD (i.e., MD only and MD-RD) obtained significantly lower scores than the controls,  $Qs(4, 178) = 9.74; 10.95, p < .01$ , respectively; and the RD-only group,  $Qs(4, 178) = 5.82; 6.59, p < .01$ , respectively. The differences between the two MD groups, and between the RD-only group and the control group, were not significant ( $ps > .01$ ). The second ANOVA also yielded a significant group effect of medium size for overall error rate. The control group made significantly fewer errors than the MD-only group and the MD-RD group,  $Qs(4, 178) = 6.96; 7.18, p < .01$ , respectively.

**Written multidigit arithmetic calculation.** The ANOVA displayed a significant achievement group effect of medium size for

the written arithmetic calculation tasks. Post hoc testing revealed that the mean difference between the MD-only group and the controls was the only difference that reached the .01 alpha level,  $Q(4, 178) = 6.62, p < .01$ , whereas the MD-RD group only showed a tendency toward a significant group difference,  $Q(4, 178) = 4.17, p < .05$ .

**Mathematic word problems.** An ANOVA on the one-step mathematic word problem-solving task showed a significant medium size group effect. Post hoc testing revealed that both groups with MD (i.e., MD only and MD-RD) obtained significantly lower scores than the controls,  $Qs(4, 178) = 8.60; 6.09, p < .01$ , respectively; and the RD-only group,  $Qs(4, 178) = 6.75; 4.53, p < .01$ , respectively. The two MD groups did not differ from each other, and neither did the control group and the RD-only group ( $ps > .01$ ). A similar pattern of performance emerged on the multistep mathematic word problem-solving task; that is, both the MD-only group and the MD-RD group performed worse than the controls,  $Qs(4, 178) = 8.53; 8.18, p < .01$ , respectively; and the RD-only group,  $Qs(4, 178) = 6.16; 5.71, p < .01$ , respectively. The children in the RD-only group performed on a par with the control children ( $ps > .01$ ).

**Place value.** A small but significant group effect was obtained on the place value task; however, the Tukey-Kramer post hoc test revealed that none of the group differences reached the .01 alpha level.

**Calculation principles.** On the calculation principles task, a medium-sized significant group effect emerged. Subsequent post hoc testing showed that the controls outperformed both children with MD only and children with MD-RD,  $Qs(4, 178) = 4.88; 6.34, p < .01$ , respectively. In addition, the RD-only group obtained significantly higher scores on this task than the MD-RD group,  $Q(4, 178) = 5.26, p < .01$ . No other group differences reached significance on this task ( $ps > .01$ ).

**Approximate arithmetic.** The ANOVA yielded a significant group effect of medium size on the approximate arithmetic task. Both the MD-only group and the MD-RD group performed significantly worse than the controls,  $Qs(4, 178) = 6.13; 7.23, p < .01$ , respectively. The MD-RD group was also outperformed by

Table 2  
Mean Performance and Standard Deviations on the Mathematic Tasks by Achievement Group

Task	MD only		MD-RD		RD only		Controls	
	M	SD	M	SD	M	SD	M	SD

11. Visual number matching											—	-.22
12. Age												—

Note.  $n = 182$ ,  $df = 180$ . Correlation coefficients larger than .19 were significant at the 1% level.

the RD-only group,  $Q(4, 178) = 4.80$ ,  $p < .01$ . No other group differences were significant on this task ( $ps > .01$ ).

*Telling time.* Finally, a significant group effect of medium size was found on the time-telling task. Both groups of children with MD (MD only and MD-RD) performed significantly lower compared to the controls,  $Qs(4, 178) = 6.16$ ;  $5.71$ ,  $p < .01$ , respectively; and the RD-only group,  $Qs(4, 178) = 6.16$ ;  $5.71$ ,  $p < .01$ , respectively. No significant group differences emerged, however, between the controls and the RD-only group ( $ps > .01$ ).

*Supporting cognitive functions.* In order to examine expected group differences in basic cognitive functions ANOVAs were calculated on the three cognitive tasks employed in the study. A significant group effect of medium size was obtained on the number-matching task, and both the MD-only group and the MD-RD group performed significantly worse than the controls,  $Qs(4, 178) = 4.49$ ;  $6.54$ ,  $p < .01$ , respectively. No significant group differences emerged on the visual-matrix span task and the trail-making task ( $ps > .01$ ).

Additional Analyses

In order to obtain a more detailed picture of the MD displayed by the MD-only children and the MD-RD children, additional

analyses were performed on the arithmetic fact retrieval task, the place value task, the calculation principles task, the approximate arithmetic task, and the time-telling task.

*Arithmetic fact retrieval and the influence of general processing speed.* The significantly slower performance of the MD-only and MD-RD children on the visual number-matching task indicated that they had a weakness in general processing speed. To examine the possibility that these children's poor performance in arithmetic fact retrieval was a consequence of general slowness, an analysis of covariance (ANCOVA) with the number-matching task as a covariate was performed on the arithmetic fact retrieval task. The assumption regarding homogeneous regression slopes between groups for the covariate was fulfilled ( $p = .40$ ). The ANCOVA revealed a significant group effect,  $F(3, 177) = 19.45$ ,  $p < .01$ ,  $\eta^2 = .25$ ,  $MSE = 55.94$ , and significant contributions also emerged for the number matching task,  $F(1, 177) = 10.24$ ,  $p < .01$ ,  $\eta^2 = .06$ ,  $MSE = 55.94$ . Post hoc testing showed that the performance of the MD-only group (adjusted  $M = 16.70$ ) and the MD-RD group (adjusted  $M = 16.48$ ) was significantly lower than that of the controls (adjusted  $M = 26.23$ ),  $Qs(4, 177) = 8.73$ ;  $9.46$ ,  $p < .01$ , respectively; and the RD-only group (adjusted  $M = 23.72$ ),  $Qs(4, 177) = 5.40$ ;  $5.80$ ,  $p < .01$ , respectively.

Table 4  
Results of the Analysis of Variance Performed on the Mathematic and Cognitive Tasks

Task	$F(3, 178)$	MSE	$\eta^2$	Post hoc
Arithmetic fact retrieval, solved problems within 3 s	27.02**	58.85	.31	CON = RD only > MD only = MD-RD
Total number of errors	12.35**	18.42	.17	CON > MD only = MD-RD, CON = RD only
Written arithmetic calculation	7.81**	8.79	.12	CON > MD only = MD-RD, CON = RD only
One-step word problems	15.79**	7.52	.21	CON = RD only > MD only = MD-RD
Multistep word problems	18.60**	2.19	.24	CON = RD only > MD only = MD-RD
Place value	4.10**	5.14	.06	CON = RD only = MD only = MD-RD
Calculation principles	9.54**	5.59	.14	CON > MD only = MD-RD, RD only > MD-RD
Approximate arithmetic	11.73**	10.54	.16	CON > MD only = MD-RD, RD only > MD-RD
Telling time	16.13**	14.99	.21	CON = RD only > MD only = MD-RD
Number matching	7.90**	1,700.56	.12	CON > MD only = MD-RD
Visual-matrix span	2.57	4.10	.04	CON = RD only = MD only = MD-RD
Trail making	2.85	2,259.38	.05	CON = RD only = MD only = MD-RD

Note. CON = controls; RD only = children with reading difficulties only (i.e., normal mathematical ability); MD only = children with mathematical difficulties only (i.e., normal reading ability); MD-RD = children with both mathematical and reading difficulties  
\*\*  $p < .01$ .

A 3 (type of number combination)  $\times$  4 (achievement group) mixed ANOVA was also performed on measures of arithmetic fact retrieval to examine possible interaction effects. However, no significant interaction effect or main effect of type of number combination (i.e., addition, subtraction, multiplication) was found ( $p < .01$ ).

*Place value, calculation principles, and approximate arithmetic.* For the same reason as for the arithmetic fact retrieval task, 3  $\times$  4 mixed ANOVAs were performed on the three submeasures of the place value task and the three submeasures of the calculation principles task. However, because the submeasures on these two tasks included different numbers of items, the ANOVAs were performed on proportion correct instead of raw scores. A 2 (addition vs. subtraction)  $\times$  4 (achievement group) mixed ANOVA was also performed on the approximate arithmetic task. The results of the three mixed ANOVAs did not display any significant interactions; that is, the group mean differences did not vary between the different submeasures of the three tasks.

*Telling time.* A fifth 2 (analog clock vs. digital clock)  $\times$  4 (achievement group) mixed ANOVA was computed on the time-telling task. This analysis showed a significant interaction between type of clock and group,  $F(3, 178) = 3.89, p < .01, \eta^2 = .06, MSE = 1.82$ . Descriptive statistics for the two submeasures are presented in Table 5. Test of simple effects revealed significant group effects for both the analog clocks,  $F(3, 356) = 19.82, p < .01, MSE = 2.21$ ; and the digital clocks,  $F(3, 356) = 36.31, p < .01, MSE = 2.21$ . For the analog clocks, subsequent Tukey-Kramer tests showed that the MD-RD group performed worse than the RD-only group,  $Q(4, 356) = 5.58, p < .01$ ; as well as the control group,  $Q(4, 356) = 10.25, p < .01$ ; whereas the MD-only group performed worse than the controls,  $Q(4, 356) = 7.28, p < .01$ ; but not the RD-only group ( $p > .01$ ). On the digital clocks, in contrast, both the MD-RD group and the MD-only group performed worse than the controls,  $Qs(4, 356) = 11.13; 11.02, p < .01$ , respectively; and the RD-only group,  $Qs(4, 356) = 9.43; 9.48, p < .01$ , respectively. Furthermore, test of simple effect showed that the RD-only group obtained significantly higher scores on the digital clocks compared to the analog clocks,  $F(1, 356) = 8.73, p < .01, MSE = 2.21$ , whereas the three other groups performed equally on the two types of clocks ( $p > .01$ ).

### *Written Multidigit Calculation and the Influence of Arithmetic Facts Retrieval*

Proficiency in written multidigit calculation is dependent on the ability to quickly retrieve arithmetic facts from long-term memory

Table 5  
Mean Performance and Standard Deviations on the Time-Telling Task by Achievement Group

Type of clock	MD only		MD-RD		RD only		Controls	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Analog	4.49	2.06	3.98	1.98	5.33	2.26	6.03	1.63
Digital	4.07	2.72	4.18	2.39	6.47	2.26	6.41	1.90

*Note.* MD only = children with mathematical difficulties only (i.e., normal reading ability); MD-RD = children with both mathematical and reading difficulties; RD only = children with reading difficulties only (i.e., normal mathematical ability).

(Ashcraft, 1992, 1995; Geary, 1993; Jordan, Hanich, & Uberti, 2003; McCloskey, Caramazza, & Basili, 1985). This connection is demonstrated by the correlation of .46 found between arithmetic fact retrieval and multidigit calculation (see Table 3). Therefore, in order to investigate whether the poor performance of the MD-only group and MD-RD group on the written multidigit calculation was due to their poor skill in arithmetic fact retrieval, an ANCOVA was computed with the arithmetic fact retrieval task as a covariate. The assumption regarding homogeneous regression slopes between groups for the covariate was fulfilled ( $p = .44$ ). The ANCOVA did not yield a significant group effect ( $p > .01$ ); the influence of the covariate, however, was significant,  $F(1, 177) = 24.38, p < .01, \eta^2 = .12, MSE = 7.77$ . Thus, the group differences in written multidigit calculation were completely accounted for by group differences in arithmetic fact retrieval.

### *Word Problem Solving and the Influence of Calculation Ability and Understanding Calculation Principles*

Mathematic word problem solving involves a complex interplay of language comprehension, problem representation, selection of calculation operations (i.e., understanding of calculation principles), and execution of calculation operations (Kintsch & Greeno, 1985; Mayer & Hegarty, 1996; Swanson, 2004). As such, it is possible that the observed problems that the MD-only group and the MD-RD group displayed on the two problem-solving tasks were a consequence of problems with some of the previously mentioned processes. In an attempt to examine this possibility, two ANCOVAs were performed with the written multidigit calculation task and the calculation principles task as covariates. The assumptions regarding homogeneous regression slopes between groups was met for both mathematic word problem tasks ( $p > .23$ ). The ANCOVA on the simple one-step mathematic word problem-solving task demonstrated a significant group effect,  $F(3, 176) = 5.45, p < .01, \eta^2 = .08, MSE = 5.05$ ; and significant contributions also emerged for the calculation task,  $F(1, 176) = 72.33, p < .01, \eta^2 = .29, MSE = 5.05$ ; and the calculation principles task,  $F(1, 176) = 7.63, p < .01, \eta^2 = .04, MSE = 5.05$ . Post hoc testing showed that the performance of the MD-only group (adjusted  $M = 5.03$ ) was significantly lower than that of the controls (adjusted  $M = 6.70$ ),  $Q(4, 176) = 4.72, p < .01$ ; and the RD-only group (adjusted  $M = 6.94$ ),  $Q(4, 176) = 4.53, p < .05$ , when the .05 alpha level was used. The performance level of the MD-RD children was not significantly lower than that of the controls or the RD-only group ( $p > .01$ ).

A significant group effect emerged on the multistep mathematic word problem-solving task,  $F(3, 176) = 7.82, p < .01, \eta^2 = .12, MSE = 1.81$ . Moreover, the calculation task,  $F(1, 176) = 26.28, p < .01, \eta^2 = .13, MSE = 1.81$ , and the calculation principles task,  $F(1, 176) = 8.22, p < .01, \eta^2 = .04, MSE = 1.81$ , turned out to be significant covariates. Follow-up comparisons revealed that the MD-RD group (adjusted  $M = 1.32$ ) and MD-only group (adjusted  $M = 1.33$ ) scored significantly poorer than the control group (adjusted  $M = 2.42$ ),  $Qs(4, 176) = 4.47$  and  $4.54, p < .01$ , respectively.

As both word problem-solving tasks displayed a rather strong correlation ( $rs = .61; .56$ ; see Table 3) with the arithmetic fact retrieval task and the written multidigit calculation task, two ANCOVAs were calculated to examine whether the observed

group differences in word problem solving could be accounted for by skill in arithmetic fact retrieval and multidigit calculation skill. The regression slopes were homogeneous for both covariates and both word problem-solving tasks ( $p > .16$ ).

On the one-step word problems no significant group effect emerged ( $p > .01$ ). The influence of the arithmetic fact retrieval task,  $F(1, 176) = 28.56, p < .01, \eta^2 = .14, MSE = 4.53$ ; and the written multidigit calculation task,  $F(1, 176) = 50.14, p < .01, \eta^2 = .22, MSE = 4.53$ , was, however, significant.

A significant group effect was found on the multistep word problem-solving task,  $F(3, 176) = 4.02, p < .01, \eta^2 = .06, MSE = 1.73$ ; and significant contributions also emerged for the arithmetic fact retrieval task,  $F(1, 176) = 16.35, p < .01, \eta^2 = .09, MSE = 1.73$ ; and the multidigit calculation task,  $F(1, 176) = 15.91, p < .01, \eta^2 = .08, MSE = 1.73$ . Post hoc testing showed that the performance of the MD-only group (adjusted  $M = 1.43$ ) and the MD-RD group (adjusted  $M = 1.47$ ) was significantly lower than that of the controls (adjusted  $M = 2.24$ ),  $Qs(4, 176) = 3.96; 3.97$ , respectively, when the .05 alpha level was used.

*Further Analyses of Multistep Word Problem Solving With Hierarchical Regression Analysis*

To further examine factors that might account for ability group differences in multistep word problem solving, two hierarchical regression analyses were calculated. That is, could the observed group differences in multistep word problem solving be accounted for by children's problems with fact retrieval, multidigit calculation, and understanding calculation principles? Two group contrast variables were created, one that captured the difference between the MD-only group and the control group (MD only vs. CON) and one that captured the difference between the MD-RD group and the control group (MD-RD vs. CON). These two contrast variables were coded as a trichotomy: +1, -1, 0 (Pedhazur, 1982). In the first contrast variable, MD only versus CON, the MD-only group was coded as +1, the control group as -1, and the RD-only group and the MD-RD group as 0. In the second contrast variable, the MD-RD group was coded as +1, the controls as -1, and the remaining two groups as 0. In the first regression model, the first block included the arithmetic fact task, the calculation task, and the calculation principles task; these three tasks were entered simultaneously. The second block included the MD only versus CON contrast variable, and the third block included the MD-RD versus CON contrast variable. The first block in the second model included the same tasks as the first model, whereas the order of the contrast variables in Blocks 2 and 3 was inverted compared to Model 1. The results of the analysis are presented in Table 6.

The three variables included in the first block accounted together for 39% of the variance in mathematic word problem performance. More important, both contrast variables, MD only versus CON, and MD-RD versus CON, accounted for 2% of the variance when entered into the regression model after the arithmetic fact retrieval task, the calculation task, and the calculation principles task, when the .05 alpha level was used (i.e.,  $ps = .023; .033$ , respectively).

To summarize, compared to the controls, and in many cases also the RD-only group, children with MD only or MD-RD performed significantly poorer on a number of tasks tapping different domains of mathematics, such as arithmetic fact retrieval, approxi-

Table 6  
*Hierarchical Regression Analysis of Performance on the Multistep Mathematic Word Problem-Solving Task*

Model	Predictor	dfs	$\Delta R^2$	F	$R^2$
Model 1

	Arithmetic fact retrieval				
	Multidigit calculation				
Block 2	MD only vs. CON	4,169	.02*	28.75**	.41**
Block 3	MD-RD vs. CON	5,168	.00	23.41**	.41**
Model 2					
Block 1	Calculation principles	3,170	.39**	35.68**	.39**
	Arithmetic fact retrieval				
	Multidigit calculation				
Block 2	MD-RD vs. CON	4,169	.02*	28.49**	.41**
Block 3	MD only vs. CON	5,168	.00	23.41**	.41**

Note. MD only = children with mathematical difficulties only (i.e., normal reading ability); CON = controls; MD-RD = children with both mathematical and reading difficulties.  
\*  $p < .05$ . \*\*  $p < .01$ .

mate arithmetic, calculation principles, mathematic word problem solving, and telling time. The MD-only and MD-RD children's lower performance on the arithmetic fact retrieval task was not removed when general processing speed was controlled for in an ANCOVA. The MD-only children also obtained lower scores on the written multidigit calculation task in comparison to the controls, but this group difference was eliminated when the arithmetic fact retrieval task was used as a covariate in the ANCOVA. The group differences on the one-step mathematic word problem-solving task was eliminated when the ANCOVA included the multidigit calculation task and the calculation principles task, or the multidigit calculation task in combination with the arithmetic fact retrieval task, as covariates. In contrast, both groups of children with MD performed significantly poorer than the controls on the multistep mathematic word problem-solving task even when the influence of the calculation principles task, the arithmetic fact retrieval task, and the multidigit calculation task were controlled for in the regression model. No significant group effects emerged for the place value task. Furthermore, the two groups with MD were significantly slower when performing the number-matching task but performed on a par with the controls on the visual-matrix span task and the trail-making task.

Discussion and Conclusions

The current study was an attempt to extend previous findings regarding the mathematic competencies of children with MD only, MD-RD, and RD only. As predicted, the children with MD only and MD-RD performed significantly poorer than the normally achieving children on all mathematic tasks, with one exception: the place value task. The results are now discussed in relation to the different domains of mathematics.

*Arithmetic Fact Retrieval*

The present results corroborate previous findings that a main problem for children with MD, whether they have reading problems or not, is to solve simple arithmetic fact problems (e.g., 5 +

4;  $9 - 4$ ;  $3 \times 4$ ) by direct retrieval of the answer from long-term memory (Andersson & Lyxell, 2007; Geary et al., 1991; Jordan & Montani, 1997; Ostad, 1997; Siegler, 1988; Temple, 1991).

An important finding is that both groups of children with MD still performed significantly poorer than the controls when the effect of general processing speed was controlled for in the analysis. Controlling for processing speed only reduced effect sizes with 6% from .31 to .25. Thus, the large effect size obtained for this task ( $\eta^2 = .31$ ) indicates that children with MD or MD-RD have a severe deficit related to their ability to establish and quickly retrieve arithmetic facts from long-term memory that cannot be attributed to general slowness. Not only did the two MD groups solve considerably fewer simple arithmetic fact problems by direct retrieval of the answer, they also made significantly more errors than the control group, even when the answer was not provided within the 3-s response interval. This latter finding indicates either that these children have incorrect answers associated with the problems stored in long-term memory, or that they have procedural problems preventing them from calculating correct answers by some other strategy (e.g., verbal counting).

### *Written Multidigit Calculation*

As expected, the MD-only group displayed a weakness in solving vertically presented multidigit calculation problems by means of paper and pencil (e.g.,  $258 + 341$ ;  $545 - 378$ ). The finding that the MD-RD group only showed a tendency ( $p < .05$ ) toward lower scores on the multidigit calculation task in comparison to the controls was, however, unexpected. Nevertheless, an important finding is that the lower performance of the MD-only group (and the MD-RD group) was eliminated when the influence of arithmetic fact retrieval was controlled for in the analysis. Thus, the medium-sized group differences ( $\eta^2 = .12$ ) in written multidigit calculation were completely accounted for by group differences in arithmetic fact retrieval ( $\eta^2 = .12$ ), suggesting that deficits in forced arithmetic fact retrieval are one underlying factor to the problems children with MD display with multidigit calculation. This interpretation is consistent with models of number processing and calculation (McCloskey, 1992; McCloskey et al., 1985) and research literature concerning the relationship between fact retrieval and multidigit calculation (Ashcraft, 1992, 1995; Geary, 1993; Gersten, Jordan, & Flojo, 2005; Jordan, Hanich, & Uberti, 2003).

### *Mathematic Word Problem Solving*

Mathematic word problem solving skill was examined with two types of written problems: one-step problems (e.g., "John had 65 crowns left when he had bought a book for 36 crowns. How much did he have to start with?") and multistep problems (e.g., "Mark weighs 38 kg. His dad weighs 35 kg more. How much do they weigh together?"). The difference between the two tasks was that the latter required at least two calculation steps in order to reach a correct solution, whereas the former could be solved in one calculation step.

Consistent with the prediction and previous research, the present study provides further empirical evidence that mathematic problem solving is an area of severe weakness for both groups of children with MD (cf. Fuchs & Fuchs, 2002; Jordan & Hanich,

2000; Parmar et al., 1996; Russell & Ginsburg, 1984), as they performed significantly worse than the control group and the RD-only group on both problem-solving tasks (one-step and multistep problems). It should be noted that the effect size measures for the two word problem-solving tasks were .21 and .24, respectively, which are close to large effect sizes (i.e.,  $\eta^2 = .25$ ). An important and novel finding is that the MD-only group still had a significantly lower level of performance when the influence of written multidigit calculation ( $\eta^2 = .29$ ) and understanding of calculation principles ( $\eta^2 = .04$ ) were controlled for in the analysis, whereas the MD-RD group now performed on a par with the controls. A small group effect size was now obtained ( $\eta^2 = .08$ ). The difference between the MD-only group and the controls on the one-step word problem-solving task disappeared when the written multidigit calculation task ( $\eta^2 = .22$ ) in combination with the arithmetic fact retrieval task ( $\eta^2 = .14$ ) were included in the ANCOVA as covariates.

Another key finding is that both groups of MD continued to perform significantly poorer than the controls on the multistep mathematic word problem-solving task when the effect of multidigit calculation skill ( $\eta^2 = .13$ ) and understanding of calculation principles ( $\eta^2 = .04$ ) were controlled for in the analysis. The effect size for ability group was now reduced to .12. Both groups of MD still performed poorer on the multistep word problem-solving task ( $\eta^2 = .06$ ) when the influence of the arithmetic fact retrieval task ( $\eta^2 = .09$ ), and the multidigit calculation task ( $\eta^2 = .08$ ), was controlled. Furthermore, the two hierarchical regression models revealed a small ( $\Delta R^2 = .02$ ) but significant difference between the controls and the two groups with MD, even when the influence of the calculation principles task, the arithmetic fact retrieval task, and the multidigit calculation task were controlled for in the regression model.

The results related to the one-step mathematic problem-solving task suggest that the MD-only and the MD-RD children's problem with this type of mathematic task is completely accounted for by their problems with multidigit calculation, arithmetic fact retrieval, and understanding calculation principles.

The fact that the performance of the MD-only and the MD-RD children on the multistep problem-solving task continued to be significantly lower than the controls' performance after controlling for arithmetic fact retrieval, calculation skill, and understanding of calculation principles indicates that the poor problem-solving skills of children with MD to some extent also are related to other processes involved in mathematic problem solving. For example, the integration of the different propositions (i.e., relation, number, and question propositions) contained in the problem into a problem representation, and developing a solution plan, are two fundamental processes of mathematic problem solving that might be impaired in children with MD (Kintsch & Greeno, 1985; Mayer & Hegarty, 1996; Swanson, 2004).

Contrary to the prediction, the MD-only group did not outperform the MD-RD group on the two problem-solving tasks. One plausible account of this negative finding is that the problem-solving tasks used in the present study were more complex in terms of calculation operations and problem-solving requirements compared to those in previous studies, whereas the linguistic demands were low (e.g., Fuchs & Fuchs, 2002; Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003). Hence, the combination of low linguistic demands and high operational and problem-solving

demands seems to eliminate the linguistic advantage the MD-only children have been found to have over the MD-RD children. Thus, the major obstacle for the MD-RD children in solving the present word problem-solving tasks is not related to linguistic demands.

### *Place Value*

The child's understanding of the base-10 number system and place value was tapped by three subtests requiring the child to identify the value of a particular digit in a multidigit number (e.g., "What is the value of the digit 9 in 349?"); to identify which number consists of a certain number of thousands, hundreds, tens, and ones; and to identify the larger number of pairs of numbers (e.g., 799999–811111). In contrast to studies by Jordan and colleagues (Hanich et al. 2001; Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003), the present study found that the two MD groups performed on a par with the control group on the place value task. This finding is consistent with results reported by Russell and Ginsburg (1984), who found that fourth graders with MD-RD did not show a deficit in the understanding of place value. Thus, the present results, in combination with previous studies on second, third, and fourth graders with MD, suggest that children with MD catch up with their normally performing peers on this fundamental aspect of mathematics as they grow older.

### *Calculation Principles*

To demonstrate his or her understanding of the relationships within and between arithmetic operations, the child had to solve problems tapping three different calculation principles: the commutativity principle ( $26 + 32 = 58$ , so what is  $32 + 26 = ?$ ), the inversion principle ( $23 + 14 = 37$ , so what is  $37 - 14 = ?$ ), and the double-plus-one principle ( $37 + 37 = 74$ , so what is  $37 + 38 = ?$ ). The present data showed that children in Grades 3 and 4 with MD only and MD-RD have a less developed understanding of the relationships within and between arithmetic operations (i.e., calculation principles). The observed group effect was of medium size, as the effect size amounted to .14. These findings are consistent with results reported by Jordan and colleagues (Hanich et al., 2001; Jordan, Hanich, & Kaplan, 2003) but contradict the findings of Russell and Ginsburg (1994). One plausible account of this inconsistency is that the children studied by Russell and Ginsburg were older (fourth graders) than the children in the present study (third and fourth graders) and in the studies reported by Jordan and colleagues (second and third graders). Thus, it is possible that most children with MD, as they get older, obtain an understanding of calculation principles comparable to that of normally achieving children; that is, that they grow out of their earlier achievement weaknesses in this specific domain of mathematics. To test this explanation a two-way ANOVA with ability group and grade level as factors was calculated to display a possible interaction effect. However, the ANOVA did not provide support for the account, as the interaction between ability group and grade was nonsignificant ( $p > .01$ ). Thus, the group mean differences did not vary as a function of grade.

### *Approximate Arithmetic*

This domain of mathematics was examined by asking the child to choose the closest approximate answer, out of two proposed

answers, to two-digit addition and subtraction combinations within 5 s (e.g., Which answer of 72 or 60 is closest to the correct answer to  $52 + 17 = ?$ ). Although the obtained effect size for this task "only" amounted to .16, the present results provide additional support to the claim that problems with estimation might be a core deficit for children with MD only and MD-RD (cf. Hanich et al., 2001; Jordan, Hanich, & Kaplan, 2003). As the performance of approximate arithmetic is assumed to require a visual-spatial representation in the form of a mental number line (Dehaene et al., 1999), future research should, therefore, test the hypothesis that children with MD have a deficit related to visual-spatial representation, and should test whether this deficit is general in nature or specifically related to numerical magnitude (cf. Jordan, Hanich, & Kaplan, 2003). Results in line with this hypothesis have been demonstrated by Andersson and Lyxell (2007), who found that children with MD only and MD-RD have poor visual working memory compared to age-matched controls. The MD-RD children were also shown to have poorer visual working memory than controls 1 year younger in age.

### *Telling Time*

Time-telling skills were assessed by requiring the child to express the time of four analog clocks in words (e.g., quarter past ten) and in digital form (e.g., 10:15) and to express the time in words of four digital clocks.

A new and important finding is that children with MD only and MD-RD have rather substantial problems with telling time ( $\eta^2 = .21$ ). The time-telling problems were equal for analog and digital clocks. According to previous studies, most children are able to identify almost all analog and digital times (e.g., 21:00; 08:30; 10:15; 15:40; 21:55; 07:35) at the age of 8 to 10 years (Case et al., 1986; Friedman & Laycock, 1989; Siegler & McGilly, 1989; Vakali, 1991). Thus, one would expect that the children who participated in the present study should manage to correctly identify most of the clocks used in the study. The performance of the controls and the RD-only children were consistent with these previous studies. The MD-only and MD-RD children, in contrast, only managed to obtain approximately 50% of the maximum score (8 out of 16). Of particular interest is their low performance for the digital clocks, as previous research has demonstrated that the ability to tell the time of digital clocks develops much earlier than that for analog clocks (7 to 8 years; Friedman & Laycock, 1989).

The time-telling problems displayed by both groups of MD children are logical considering that telling time is a complex skill that involves a number of operations that have much in common with basic arithmetic (Friedman & Laycock, 1989; Siegler & McGilly, 1989). As such, deficit in time telling ought to be found in children with MD. Because the MD-only and MD-RD children displayed a comparable number of problems with the analog and digital clocks, which are assumed to involve different processes, this suggests that they have deficits related to establishing and retrieving memory representations (analog and digital clocks; Friedman & Laycock, 1989; Siegler & McGilly, 1989) as well as counting procedures (analog clocks; Friedman & Laycock, 1989). These two types of deficit are also clearly demonstrated within the other domains of mathematics (e.g., fact retrieval, multidigit calculation, word problem solving).

### *Basic Cognitive Functions*

In addition to the different mathematic domains, the present study examined three basic cognitive functions: visual working memory, general processing speed, and executive functions. Visual working memory was tapped by a dual task (visual-matrix span) requiring the child to remember the location of dots in a matrix and to answer a process question. Visual working-memory capacity was measured as the most complex matrix remembered correctly. A number-matching task that involved crossing out two identical digits in rows of seven digits as fast and accurately as possible was used to measure general processing speed. The classic trail-making task was used to assess one important executive function, the ability to switch between operations or retrieval strategies. The task was to connect as fast and accurately as possible 25 circles, 13 with a number in the center and 12 with a letter in the center, so that each number alternated with its corresponding letter (i.e., 1-A-2-B-3-C . . . 12-L-13).

Similar to previous studies, this study demonstrates that the two groups with MD have deficiencies connected to general processing speed, as they performed the number-matching task significantly slower than the controls ( $\eta^2 = .12$ ; cf. Andersson & Lyxell, 2007; Bull & Johnston, 1997; Swanson & Beebe-Frankenberger, 2004). In contrast to Andersson and Lyxell and Swanson (1994), the two MD groups performed on a par with the control group on the visual-matrix span task. This finding, however, is consistent with results reported by Swanson and Beebe-Frankenberger and by Swanson and Sachse-Lee (2001). The data concerning the trail-making task do not replicate findings reported by Andersson and Lyxell or McLean and Hitch (1999), suggesting that children with MD only and MD-RD have a problem related to the executive function of switching between operations or retrieval strategies.

The combined results of the three cognitive tasks suggest that the MD displayed by the MD-only and MD-RD children cannot be attributed to deficits in visual working memory and the switching aspect of executive function. Neither are the processing speed problems a plausible underlying factor to these children's difficulties with mathematics, as the effect size was only .12, and controlling for processing speed did not eliminate the large group effect on the arithmetic fact retrieval task but only reduced it by 6%. Furthermore, the correlations between the different mathematic tasks and the number-matching task were rather low, ranging in size from  $-.17$  to  $.36$  (see Table 3).

### *Children With RD Only and Mathematics*

The RD-only children performed at the same level as the control group on all tasks of mathematics used in the study. Thus, in line with the majority of previous research, the present study does not provide any data suggesting that children with RD only have any weakness in mathematics, not even forced fact retrieval or word problem solving (Jordan & Hanich, 2000; Jordan, Hanich, & Kaplan, 2003). However, the possibility still remains that this group of children encounters problems with areas of mathematics that are mediated via language (i.e., reading) in later elementary school (see Jordan, Hanich, & Kaplan, 2003).

### *Educational Implications*

The present findings have at least two important educational implications. First, as skill in arithmetic fact retrieval seems to

have a major impact on more complex mathematic skills (e.g., multidigit calculation, word problem solving), and deficits in fact retrieval are a cardinal characteristic of children with MD, this suggests that mathematic instructions should place more emphasis on teaching children with MD this basic skill. In order to promote word problem-solving skill in children with MD, special instructions should also emphasize multidigit calculation fluency and understanding of calculation principles. The present findings indicate that, in addition to these more basic skills, it is important to provide direct instructions concerning conceptual aspects of problem solving, such as problem representation and developing solution plans. Thus, in order to help children with MD to overcome their problems with mathematic word problem solving, the remedial instructions should focus on both basic and complex mathematic skills that facilitate word problem solving (Geary, 2004; Jordan, Hanich, & Uberti, 2003). Second, the ability to tell the time is an important area of mathematics that ought to get more attention when providing special instructions for children with MD. This skill shares many features with basic arithmetic, a statement that is supported by the present correlations between the time-telling task and the other mathematic tasks (see Table 3; cf. Friedman & Laycock, 1989; Siegler & McGilly, 1989). Hence, besides the value of mastering this skill that is used on a daily basis, improving the time-telling skills of MD children might have positive effects on other areas of mathematics.

### *Limitations of the Present Study and Further Research*

At least three limitations of the present study should be acknowledged. One limitation is that the MD-only group only included 10 boys, which may reduce the possibility of generalizing the present findings to boys with MD only. Another potential limitation of the present study is its use of time limits for the multidigit calculation task and the mathematic word problem-solving tasks. Although the present findings indicate that MD in children cannot be attributed to general slowness, and the tasks in question were designed so that the test items became successively more difficult, there is always a possibility that the MD-only and MD-RD children might have obtained higher scores if they had had the opportunity to attempt all test items. A third limitation is the lack of verbal working-memory tasks. The visual working-memory capacity of the MD children was shown to be equal to that of the controls; it is, however, possible that they have a poorer verbal working memory compared to the controls (cf. Andersson & Lyxell, 2007; Siegel & Ryan, 1989; Swanson & Sachse-Lee, 2001). A verbal working-memory deficit could potentially account for some of the problems that the two MD groups displayed with mathematic word problem solving.

Future studies should take into account these limitations. In addition, an important objective for future research on children with MD is to examine multiple areas of mathematics from a longitudinal developmental perspective (cf. Jordan, Hanich, & Kaplan, 2003). This type of study is necessary in order to examine the stability of MD in children, that is, identifying children with MD whose difficulties reflect either a delay or a deficit in cognitive development (Kulak, 1993). Furthermore, by examining multiple areas of mathematics in longitudinal studies it will be possible to identify those areas that continue to be problematic for children with MD and those areas that do not. As such, it will provide a

more comprehensive test of the first hypothesis of the present study, that children with MD only and MD–RD display more severe problems with arithmetic facts retrieval, mathematic word problem solving, and written multidigit arithmetic calculation compared to areas such as place value and calculation principles.

A longitudinal research design assessing multiple areas of mathematics will also present an opportunity to further examine whether the poor performance of the two MD groups on mathematic word problem solving and multidigit written calculation is due to weaknesses in basic mathematical skills such as arithmetic fact retrieval, understanding of calculation principles, and computation (i.e., Hypotheses 3 and 4). In addition, to examine potential mathematic problems for RD-only children future studies should include more linguistically demanding word problem-solving tasks. The inclusion of more linguistically demanding tasks should also provide a test of the hypothesis that children with MD–RD have a disadvantage compared to children with MD only on tasks that are mediated by language. Further studies are also needed to expand researchers' knowledge regarding the time-telling skills of children with MD. For example, this skill should be examined in younger and older children with MD to determine the order of skill acquisition and the age at which MD children catch up with their normally achieving peers.

## Conclusions

The present study provides further empirical evidence that children with MD or MD–RD have weaknesses in multiple areas of mathematics. For example, a new and important finding is that children with MD only and MD–RD have substantial problems with telling time. Place value, in contrast, is the only domain that did not differentiate children with MD from the control children. Deficits in fact retrieval are a cardinal characteristic of children with MD. This deficit also seems to be an underlying factor to the problems children with MD display with multidigit calculation and mathematic word problem solving. The substantial difficulties that both groups with MD display with mathematic word problem solving can be attributed to several subprocesses involved in problem solving. Besides poor skills in multidigit calculation and arithmetic fact retrieval, and poor understanding of calculation principles, children with MD might have deficits related to specific problem-solving processes such as establishing a problem representation and developing a solution plan. The present study failed to demonstrate that children with MD only have an advantage over MD–RD children on mathematic word problem solving, a result that might be a consequence of the fact that the present word problem tasks imposed low linguistic demands but high calculation and problem-solving demands, and thereby eliminated the linguistic advantage of the MD-only children. The present study did not detect any signs that children with RD only have any weakness in mathematics.

### Members of Underrepresented Groups: Reviewers for Journal Manuscripts Wanted

If you are interested in reviewing manuscripts for APA journals, the APA Publications and Communications Board would like to invite your participation. Manuscript reviewers are vital to the publications process. As a reviewer, you would gain valuable experience in publishing. The P&C Board is particularly interested in encouraging members of underrepresented groups to participate more in this process.

If you are interested in reviewing manuscripts, please write to the address below. Please note the following important points:

- To be selected as a reviewer, you must have published articles in peer-reviewed journals. The experience of publishing provides a reviewer with the basis for preparing a thorough, objective review.
- To be selected, it is critical to be a regular reader of the five to six empirical journals that are most central to the area or journal for which you would like to review. Current knowledge of recently published research provides a reviewer with the knowledge base to evaluate a new submission within the context of existing research.
- To select the appropriate reviewers for each manuscript, the editor needs detailed information. Please include with your letter your vita. In the letter, please identify which APA journal(s) you are interested in, and describe your area of expertise. Be as specific as possible. For example, "social psychology" is not sufficient—you would need to specify "social cognition" or "attitude change" as well.
- Reviewing a manuscript takes time (1–4 hours per manuscript reviewed). If you are selected to review a manuscript, be prepared to invest the necessary time to evaluate the manuscript thoroughly.

Write to Journals Office, American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242.

# Prediction of Children's Academic Competence From Their Effortful Control, Relationships, and Classroom Participation

Carlos Valiente, Kathryn Lemery-Chalfant, Jodi Swanson, and Mark Reiser  
Arizona State University

The authors examined the relations among children's effortful control, school relationships, classroom participation, and academic competence with a sample of 7- to 12-year-old children ( $N = 264$ ). Parents and children reported on children's effortful control, and teachers and children reported on children's school relationships and classroom participation. Children's grade point averages (GPAs) and absences were obtained from school-issued report cards. Significant positive correlations existed between effortful control, school relationships, classroom participation, and academic competence. Consistent with expectations, the teacher-child relationship, social competence, and classroom participation partially mediated the relation between effortful control and change in GPA from the beginning to the end of the school year. The teacher-child relationship and classroom participation also partially mediated the relation between effortful control and change in school absences across the year.

**Keywords:** effortful control, peer and teacher relationships, classroom participation, academic competence

Children's academic competence is central to their future success. The importance of successfully navigating the challenges of the school environment is highlighted by findings that academic competence is a significant correlate of positive mental health and high school graduation (Caspi, Elder, & Bem, 1987; Ensminger & Slusarcick, 1992). Despite the importance of school success, 15% of adults report that they have not completed high school (Stoops, 2004). Although the majority of research on school success has focused on curricula, structure, teacher-child ratios, and intelligence, there is an increased awareness of the important roles children's regulatory abilities, school-related relationships, and classroom participation play in contributing to their academic competence. Indeed, Blair (2002) noted that some longitudinal evidence indicates that social and emotional factors relate to aspects of school success or failure even when controlling for general intelligence at school entry.

The literature considering indices of children's regulatory abilities and measures of academic competence is growing, as is the literature on relational and motivational correlates of school success. However, studies that bridge these literatures are rare. The current study begins to fill this gap and was designed (a) to test if

effortful control (an index of regulatory abilities) predicts changes in academic competence (i.e., grades and absences) across a school year; (b) to test if students' relationships with teachers and peers, as well as their classroom participation, predict changes in academic competence; and (c) to test if relationships and classroom participation partially mediate the relation between effortful control and academic competence. Simultaneously considering constructs from traditionally different areas of research may clarify if and how children's regulatory abilities predict their academic competence.

We used effortful control (EC) as an index of children's regulatory abilities. EC is defined as "the efficiency of executive attention—including the ability to inhibit a dominant response and/or to activate a subdominant response, to plan, and to detect errors" (Rothbart & Bates, 2006, p. 129). Children high in EC are believed to be able to voluntarily control their attention and behavior as needed. EC is measured in a variety of ways, often with measures of attentional regulation, persistence, and the ability to delay gratification, as well as with indices of the ability to voluntarily inhibit or activate behavior (Kochanska, Murray, & Harlan, 2000; Rothbart & Bates, 2006). EC processes are linked to children's emotion-related regulation, and they modulate emotional reactivity and behaviors (Rothbart & Bates, 2006).

## Relations Between Children's Effortful Control and Academic Competence

Several investigators have argued that emotional competence and processes involving executive attention are important for academic success (Blair, 2002; Raver, 2002). Huffman, Mehlinger, and Kerivan (2000) hypothesized that children's regulatory abilities contribute to competence beyond measures of IQ. In one study, 60% of teachers reported that being sensitive and not disruptive represented important aspects of academic readiness (Lewit & Baker, 1995). Children high in EC likely have many of

these skills, do not easily divert from tasks (Zimmerman, 1998), and process detailed situations more accurately than do their peers low in EC (Lemerise & Arsenio, 2000; NICHD Early Child Care Research Network, 2003).

Some evidence supports the hypothesis that components of EC (e.g., attentional regulation, persistence, or delay of gratification) are positively related to reading, math, and linguistic abilities as well as teachers' reports of competence (Fabes, Martin, Hanish, Anders, & Madden-Derdich, 2003; NICHD Early Child Care Research Network, 2003), although EC sometimes does not relate to grade retention (Willson & Hughes, 2006). Findings that preschoolers' delay of gratification predicts future verbal intellectual ability and SAT scores provide some evidence that the relations between regulatory abilities and academic competence persist over time (Rodriguez, Mischel, & Shoda, 1989; Shoda, Mischel, & Peake, 1990). Moreover, some data indicate that the relations between EC and academic competence are similar cross-ethnically. For example, Valiente, Lemery-Chalfant, and Castro (2007) found that Mexican American children's EC was related to teacher-reported academic competence and absenteeism.

The preceding review indicates that children's EC is positively related to measures of academic competence; however, not all findings are consistent or significant effects are reduced in magnitude when control variables (e.g., sex or socioeconomic status; SES) or correlates of academic competence are added to the models. In addition, the relations generally account for a modest amount of the variance, suggesting that other constructs are also important when considering academic competence. On the basis of the broader literature, it seems likely that students' relationships and classroom participation may mediate the relations between EC and academic competence.

### Relations Between Children's Relationships and Academic Competence

As noted above, in addition to EC, the relationships children develop and maintain in school have been associated with their academic competence. A supportive teacher-child relationship may buffer children from some risk factors associated with poor performance, perhaps because teachers are more likely to provide extra assistance to children with whom they have a positive relationship (Resnick et al., 1997). Consistent with this hypothesis, Hamre and Pianta (2001) predicted that a high-quality teacher-child relationship motivates teachers to invest extra resources that can promote children's school success. In contrast, a conflictual teacher-child relationship may increase stress for the child that may interfere with learning and motivation. Longitudinal data suggest that declines in the nurturant teacher-child relationship precede declines in achievement, and there is evidence that teacher-reported negativity in the teacher-child relationship is related to achievement test scores even when controlling for verbal IQ (Hamre & Pianta, 2001; Midgley, Feldlaufer, & Eccles, 1989).

Positive relationships with peers also contribute to children's academic achievement (Raver, 2002). Indeed, components of social competence such as peer acceptance and friendships are hypothesized to promote social inclusion in the classroom, which may yield resources that foster interpersonal and academic success (Ladd, 2003). Welsh, Parke, Widaman, and O'Neil (2001) found that positive social skills were associated with academic compe-

tence, and evidence supports the premise that peer acceptance and general levels of social competence are linked to performance in math, reading, and language (see Ladd, 2003, for a review).

The preceding review suggests that both children's EC and relationships are related to academic competence. In addition, some data support the hypothesis that EC is related to children's relationships, and this is necessary for relationships to mediate the relation between EC and academic competence. When children are low in EC and disruptive, they are at increased risk of developing poor relationships with their teachers and receiving low levels of instruction (Berndt & Keefe, 1995; Birch & Ladd, 1997; Murray & Greenberg, 2000). This may contribute to negative perceptions of the classroom, which interfere with motivation for subsequent learning and performance (Wentzel, 1999). Consistent with this line of reasoning, children who lack social skills are viewed as difficult to teach and receive low levels of positive feedback (Arnold, Homrok, Ortiz, & Stowe, 1999; McEvoy & Welker, 2000; Shores & Wehby, 1999), but studies that directly measure EC and examine the hypothesized relations are needed.

There is support for the hypothesis that EC is positively related to indices of social competence. For example, children high in EC are often rated high in compliance (Kochanska, Coy, & Murray, 2001; Kochanska, Murray, & Coy, 1997), sympathy (Eisenberg & Fabes, 1998; Valiente et al., 2004), and social competence (Eisenberg, Gershoff, et al., 2001; see Rothbart & Bates, 2006, for a review). In contrast, children low in EC likely have difficulty modulating negative emotions, complying with others' requests, and avoiding conflictual peer interactions. In summary, there is evidence that academic competence is associated with both EC and children's relationships, but it is not clear if EC provides unique prediction of academic competence or if relationships partially mediate the EC and academic competence associations.

### Relations Between Children's Classroom Participation and Academic Competence

Some findings indicate that students' classroom participation is associated with their grades and absences and that classroom participation might partially mediate the relations between EC and academic competence. Theorists argue that participation may reflect an internal motivation and learning-goal orientation that directs one's behavior toward classroom tasks and demands (Dweck, 1989; Finn, 1993; Gottfried, Fleming, & Gottfried, 1994). In a national report on educational statistics, Finn (1993) noted that students who rarely participate in their classrooms are at risk to perform poorly beyond risks associated with race, ethnicity, language, or family income. Furthermore, scholars suggest that motivation contributes to academic outcomes because it directs students' actions and activities, perhaps because they are motivated to pursue goals valued in the school context (Wentzel, 1999; Wigfield, Eccles, Schiefele, Roeser, & Davis-Kean, 2006). Evidence indicates that measures of engagement such as classroom participation and school liking are related to academic progress, math skills, language skills, and attendance (Ladd, Birch, & Buhs, 1999; Valiente et al., 2007). Children low in engagement are likely to have difficulty following rules and capitalizing on learning opportunities that are often correlated with indices of cognitive functioning (Bronson, Tivnan, & Seppanen, 1995; Hughes & Kwok, 2006).

After reviewing the motivation-to-succeed literature, Eccles, Wigfield, and Schiefele (1998) noted that "the highest priority in this area is attention to the influence of emotions on motivation" (p. 1075). Although progress has been made (Wigfield et al., 2006), Eisenberg (2006) suggested in the introduction to the *Handbook of Child Psychology* that much more work is necessary. Relations between EC and classroom participation might be expected, because children must modulate emotions and demands that occur in school environments to remain engaged (Alexander & Entwisle, 1988). Consistent with this line of reasoning, Valiente et al. (2007) found that EC was positively related to school liking (an index of engagement), and school liking mediated the relation between EC and academic competence.

### The Present Study

Findings from several often disparate literatures support the premise that children's EC, relationships with teachers and peers, and classroom participation represent important correlates of academic competence. However, it is unclear if these variables offer unique or overlapping prediction of academic competence. Our first aim in this study was to test if EC predicted measures of academic competence (i.e., grades and absences) at the conclusion of a school year (i.e., spring) while controlling for academic competence at the beginning of the school year (i.e., fall). Our second goal was to test if prediction from EC remained significant after adding measures of children's relationships and a measure of classroom participation to the model. We expected positive zero-order relations among children's EC, the teacher-child relationship, social competence, classroom participation, and GPA; the reverse pattern of relations was expected for school absences. In an effort to extend the literature and on the basis of some empirical evidence (Valiente et al., 2007) and theory (Eisenberg, Sadovsky, & Spinrad, 2005), we predicted that the teacher-child relationship, social competence, and classroom participation would mediate the relations between EC and academic competence.

The extant literature indicates that measures of children's SES often relate to children's performance in school and attendance. For example, income was positively related to both the classroom environment (NICHD Early Child Care Research Network, 2005) and students' achievement (Davis-Kean, 2005). In a review, Haveman and Wolfe (1995) concluded that poverty limits students' academic competence and academic years completed. Nevertheless, as noted above, low classroom participation places a child at risk for school failure regardless of family income (Finn, 1993). To examine the influence of SES, we added SES to all models and expected SES to be positively related to grades and negatively related to absences.

The literature also suggests that children's sex is associated with their academic competence; however, findings regarding sex are somewhat less consistent than findings for SES. Whereas sex differences in math and reading sometimes fail to reach significance (Davis-Kean, 2005; Simpkins, Davis-Kean, & Eccles, 2006), some research suggested that boys outperformed girls on math tasks (Frome & Eccles, 1998; Jordan, Kaplan, Oláh, & Locuniak, 2006), and other reports found that girls achieved better reading performance than boys (Frome & Eccles, 1998). Although sex differences such as these are generally small, because of these

relations, we added children's sex to all equations when testing our hypotheses.

In addition, because 47% of the sample in this study was Mexican American and the next largest ethnic group represented was European American (30%), we tested if the strength of the relations differed for Mexican American and European American children. Findings from previous work indicate that Latino students perform more poorly in reading and math than do their European American peers (Children's Action Alliance, 1999; U.S. Department of Education, 2004).<sup>1</sup> Latino students also tend to be absent, to be tardy, and to drop out of school prior to graduation more often than students of other ethnicities (Finn, 1993; U.S. Bureau of the Census, 2004).

Despite some mean level differences, and although much of the data in this area stems from European American children, it seems likely that EC, school relationships, and classroom participation are also important correlates of Mexican American children's academic competence. There is some evidence that prediction of developmental outcomes from measures of EC in other cultures (e.g., Indonesia and China) is similar to prediction of outcomes found in U.S. samples (Eisenberg, Pidada, & Liew, 2001; Zhou, Eisenberg, Wang, & Reiser, 2004). Furthermore, the relations between U.S. minority children's regulatory abilities and their socioemotional and school functioning are similar to relations found in studies that include mostly European American children (Blair, 2002; Gilliom, Shaw, Beck, Schonberg, & Lukon, 2002; Schultz, Izard, & Ackerman, 2000). Thus, we did not expect the relations among the study variables to be different for Mexican American versus European American children.

### Method

#### *Procedure and Participants*

Participants were recruited from two schools in a southwestern U.S. city. Before the study began, parents ( $N = 561$ ) received an introductory letter informing them of enrollment and participation procedures. In addition, research assistants were available in the schools during parent-teacher conferences to enroll parents and answer questions about the study. To increase the reliability of the construct scores and to reduce shared method variance, we used a multireporter (child, primary caregiver parent, and teacher) method to assess the key constructs. The questionnaires sent to parents assessed children's EC and social competence. Parent packets were available in either English or Spanish, because some parents ( $n = 40$ ) preferred to complete their packets in Spanish. A translation and back-translation method was used, and the original English version was compared with the back-translated version to determine equivalence. The process of translation and back translation continued until all differences were resolved. Teachers ( $N = 22$ ; teachers reported on an average of 12 children) reported on the teacher-child relationship, children's social competence, and classroom participation. Children reported on their EC, the teacher-child relationship, and their classroom participation. Dur-

<sup>1</sup> We use *Latino* when describing the pan-ethnic population that comprises those of Spanish ethnicity and *Mexican American* when either describing our sample (composed only of Mexican American Latinos) or when referring only to the Mexican American subethnic Latino group.

ing the school day, a research assistant read all items to children in their classroom. All questionnaires were completed between March and April, and participants were compensated for their participation.

Parents of 122 boys and 142 girls (47% of those eligible) provided consent for themselves and for their children to participate. Children were between the ages of 7 and 12 years ( $M = 9.57$  years,  $SD = 1.04$ ), attended 1 of 22 regular education classrooms, and provided assent. Forty-seven percent of the parent and child participants were Mexican American, 30% were European American, 5% were African American, 8% were Native American, and 10% were of other ethnic origins. To reduce the heterogeneity of the sample, we did not include children who were solely enrolled in special education services and did not spend any time in regular education classrooms in this study.

The sample represents the sex and ethnic population composition of the classrooms (i.e., the population of the classrooms was 48% boys and 52% Mexican American, 34% European American, 8% African American, and 6% Native American children), demonstrating that our sample of children closely resembles all of those eligible. To further compare those children whose parents provided consent with those whose parents did not, we examined the absence rate, a percentage rate published by the Arizona Department of Education, of those who participated with those eligible. The absence rate in our sample (4%) closely represents the absence rate for those eligible (5%). Because public access of GPA data is unavailable, we were not able to conduct a similar comparison for GPA.

Children were predominantly from two-parent homes (80%) in which the primary caregiver was the child's biological mother (84%). Seventeen percent of primary caregivers (percentages for secondary caregivers [75% were fathers] are in parentheses; 17%) had less than a high school education, 26% (37%) had a high school education, 28% (19%) had some college education, 16% (11%) had a 2-year-college or trade degree, 7% (7%) had a 4-year-college degree, and 6% (9%) had attended graduate school. Family income ranged from below \$15,000 to above \$150,000 per year and had a mean range of \$30,000 to \$50,000 per year.

## Measures

**SES.** Income, primary caregivers' education, and secondary caregivers' education were highly related ( $rs > .45$ ,  $p < .01$ ); therefore, after standardizing, the items were averaged to form a measure of SES ( $\alpha = .76$ ).

**Effortful control.** Children and parents reported on children's EC. Items from the Attention Shifting (e.g., "I am [Your child is] good at keeping track of several different things that are happening around me [him/her]"), Activation Control (e.g., "If I have [Your child has] a hard assignment to do, I get [he/she gets] started right away"), and Inhibitory Control (e.g., "When someone tells me [your child] to stop doing something, it is easy for me [him/her] to stop") subscales from the Early Adolescent Temperament Questionnaire (Capaldi & Rothbart, 1992) assessed children's EC. Items were rated on a 5-point Likert-type scale (1 = *almost always untrue* to 5 = *almost always true*), and the average of the items (18 for parents and 16 for children) served as a composite of parent-reported and child-reported EC ( $\alpha s = .89$  and  $.73$  for parents and children, respectively). Capaldi and Rothbart (1992) reported that

scores from the scale have good discriminant validity, and there is evidence that parent-reported EC and observed indices of EC are significantly related (Eisenberg, Gershoff, et al., 2001; Valiente et al., 2003).

**Teacher-child relationship.** Teachers reliably ( $\alpha = .90$ ) rated 20 items on a 5-point scale (1 = *definitely not true* to 5 = *definitely true*) from the Student-Teacher Relationship Scale to report on the closeness and conflict of the teacher-child relationship (e.g., Hamre & Pianta, 2001; Pianta, 2001). This scale has been used often in studies with elementary school children, and scores have demonstrated internal consistency. Children rated their relationship with their teacher on a 3-point scale ( $\alpha = .92$ ; 1 = *not at all* to 3 = *a lot of the time*) using an age-appropriate version of the Student-Teacher Relationship Scale. Evidence that the measure correlates in the expected directions with later academic performance, attitudes, and involvement supports the convergent validity of the Student-Teacher Relationship Scale (Birch & Ladd, 1997; Hamre & Pianta, 2001).

**Social competence.** Two subscales of a slightly modified (Eisenberg, Fabes, Guthrie, & Reiser, 2000) version of Harter's (1982) Perceived Competence Scale for Children were used to assess children's social competence. Socially appropriate behavior was the average of four items (e.g., "This child is usually well behaved";  $\alpha s = .87$  for parents and  $.85$  for teachers). Popularity was the average of three items (e.g., "This child has a lot of friends";  $\alpha s = .88$  for parents and  $.89$  for teachers). Parents' reports of socially appropriate behavior and popularity were highly correlated,  $r(217) = .73$ ,  $p < .001$ , as were teachers' reports,  $r(236) = .53$ ,  $p < .001$ . Thus, the scales were averaged within reporter to form separate measures of parents' and teachers' reports of social competence.

**Classroom participation.** Teachers used 11 items from the Teacher Rating Scale of School Adjustment (Birch & Ladd, 1997; Ladd, Kochenderfer, & Coleman, 1996) to rate children's classroom participation. Items were rated on a 3-point scale (0 = *doesn't apply* to 2 = *certainly applies*). Teachers' reports of children's classroom participation (e.g., "This child follows instructions," "This child challenges him/herself to do well in school") were reliable ( $\alpha = .94$ ). Children reliably ( $\alpha = .67$ ) rated items on an age-appropriate version (e.g., "I follow my teacher's instructions") of this measure.

**Academic competence.** Official school records were used to obtain measures of children's academic competence. At the conclusion of the school year, we obtained records of full school days missed and tardies from the fall and spring quarters of the school year. Because the number of full school days missed and tardies were significantly related at the first and last quarters ( $rs = .24$  and  $.27$ ,  $ps < .001$ , respectively), we standardized the number of full school days missed and tardies and then averaged the standardized scores. In the remainder of the article, we refer to this composite as *absences*. Consistent with Pierce, Hamm, and Vandell (1999), we averaged scores in language, vocabulary, and math (all  $rs > .60$ ) to form children's fall and spring GPAs (1 = *a grade of F* to 5 = *a grade of A*).

## Results

Prior to hypothesis testing, we computed a series of preliminary analyses to test for potential age and sex differences. Next, we

examined zero-order relations among the study variables. Finally, mixed model regressions were computed to test the hypotheses. We concluded by testing if the strength of the findings was different for Mexican American versus European American participants.

Complete data were available for 77% of the participants. To avoid problems associated with listwise deletion (see Schafer & Graham, 2002), we imputed missing values using the expectation maximization algorithm after specifying a normal distribution with the missing value analysis program in SPSS Version 12.0. Little's missing completely at random test was not significant,  $\chi^2(288) = 291.60$ , *ns*, which supports this method of imputing missing data. Because the patterns of findings were similar for imputed and nonimputed data, we present the results obtained on the single imputed set.

### Preliminary Analyses

Table 1 contains the means and standard deviations for the study variables. To examine sex differences, we computed separate multivariate analyses of variance (MANOVAs) by reporter. There were significant multivariate effects (Hotelling's *T*) for child-reported measures,  $F(3, 260) = 5.86$ ,  $p < .001$ , and for teacher-reported measures,  $F(2, 261) = 18.17$ ,  $p < .001$ . Univariate tests indicated that teachers reported closer teacher-child relationships with girls than with boys and rated girls higher than boys in classroom participation,  $F_s(1, 262) = 25.02$  and  $34.22$ ,  $p_s < .001$ , respectively. Girls reported higher levels of EC, closer teacher-child relationships, and more classroom participation than boys reported,  $F_s(1, 262) = 13.56$ ,  $9.36$ , and  $5.05$ ,  $p_s < .001$ ,  $.01$ , and  $.05$ , respectively. In addition, parents rated girls higher in EC than they did boys,  $t(263) = 21.60$ ,  $p < .001$ . There was also a significant multivariate effect for grades and absences,  $F(4, 259) = 7.26$ ,  $p < .001$ . Univariate tests indicated that girls per-

formed significantly better academically than boys did in fall and in spring,  $F_s(1, 262) = 21.82$  and  $24.94$ ,  $p_s < .001$ , respectively; however, there were no significant sex differences in fall or spring absence patterns.

Table 2 presents the correlations among all the variables and illustrates the similar pattern of findings for imputed versus non-imputed data. As shown in Table 2, when considering the imputed data, 63 of 78 correlations were significant. Irrespective of reporter, the measures of EC, the teacher-child relationship, social competence, and classroom participation were all significantly related to children's GPAs in fall and spring. EC, both child and parent reported, was positively related to children's social competence (parent and teacher reported), teacher-child relationship (child and teacher reported), and classroom participation (child and teacher reported). The indices of children's EC, teacher-child relationship, and social competence were significantly related to children's absences from school. The zero-order correlations provide initial support for the hypotheses.<sup>2</sup>

Table 2 also contains the within-construct relations. Consistent with previous research, child and parent reports of children's EC correlated .41, and teacher and parent reports of social competence correlated .29. In addition, teacher and child reports of the teacher-child relationship were correlated .31, and their reports of classroom participation were correlated .32. Therefore, because reports of the same construct across reporters were always significant ( $p_s < .01$ ) and because significant relations were found across reporters, to reduce the number of analyses, we created composite scores by averaging across reporters.<sup>3</sup> The remainder of the analyses use these composites.

### Regression Analyses

The observations in the present study are clustered (i.e., children are nested within classrooms); thus, prior to testing our hypotheses, we examined the intraclass correlations associated with each model. Clustered data can result in a correlation among responses from the same classroom, and standard errors and consequent significance tests may be biased if the correlation is ignored. Hox (2002) considered intraclass correlations values of .05, .10, and .15 to be small, medium, and large, respectively, but also demonstrated that even intraclass correlations of .10 can bias results. The intraclass correlations in this study ranged from .02 to .14, and the average intraclass correlation was .08 (see Tables 3 and 4 for the intraclass correlation associated with each mixed model regression). Although the intraclass correlations were generally small, because clustering can potentially bias significance tests and resulting conclusions, the remainder of the analyses were computed using mixed models in SPSS Version 12.0, with classroom as a random effect.

The variables did not exceed West, Finch, and Curran's (1995) cutoffs for skewness, kurtosis, and outliers. According to Cook's (1977) distance, there were no multivariate outliers. In each anal-

Table 1  
Descriptive Statistics for Study Variables

Variable	<i>M</i>	<i>SD</i>	Range
Socioeconomic status	3.28	1.37	0-7
Effortful control: Child report	3.41	0.52	2.00-5.00
Effortful control: Parent report	3.27	0.60	1.11-4.72
Social competence: Teacher report	3.05	0.68	1.00-4.00
Social competence: Parent report	3.00	0.78	1.00-4.06
Teacher-child relationship: Child report	2.21	0.44	1.00-3.00
Teacher-child relationship: Teacher report	3.90	0.61	1.50-5.00
Classroom participation: Child report	2.34	0.31	1.20-3.00
Classroom participation: Teacher report	2.44	0.51	1.18-3.00
GPA (fall)	3.92	0.87	1.00-5.00
GPA (spring)	3.89	0.94	1.00-5.00
Absences (fall)	0.97	1.12	0.00-6.50
Absences (spring)	1.86	1.78	0.00-12.00

Note. Statistics for socioeconomic status and absences are presented prior to standardizing scores. The standardized scores are used in all other analyses.

<sup>2</sup> Neither parent nor child reports of their own social desirability significantly correlated with the other measures.

<sup>3</sup> Because teacher and child reports of the teacher-child relationship were on a different scale, we standardized the scores before averaging the two scores. All other measures were on the same scale, so we did not standardize scores prior to creating the composites.

ysis, we controlled for children’s sex and family SES. In addition, when predicting spring GPA (or spring absences), we controlled for fall GPA (or fall absences) to examine the relation of the predictors to change in academic competence across the school year.

To address the first goal of predicting indices of academic competence from EC, we computed two mixed model regressions (see Table 3). Consistent with expectations, EC was positively related to spring GPA and negatively related to spring absences. To test the prediction that the teacher–child relationship, social competence, and classroom participation partially mediated the relation between EC and GPA (or absences), we computed additional mixed model regressions on the basis of the guidelines outlined by MacKinnon, Lockwood, Hoffman, West, and Sheets (2002). For mediation to be present, EC should predict the medi-

ator (e.g., teacher–child relationship, social competence, or classroom participation) and the mediator should predict the outcome (e.g., GPA or absences) when EC is included in the model. Full mediation exists if the relation between EC and the outcome is zero when the mediator is included in the model, whereas partial mediation exists if EC continues to predict the outcome when the mediator is in the model.

The first column of betas in Table 4 illustrates that the relation between EC and the teacher–child relationship was significant and that the teacher–child relationship was positively related to GPA and absences beyond the effects of EC (and fall GPA or absences, sex, and SES). To test for mediation and to accommodate the nonnormal distribution of the indirect effects (e.g., the product of the coefficient from the independent variable to the mediator and the coefficient from the mediator to the dependent variable are generally nonnormally distributed), we used a confidence interval method (MacKinnon et al., 2002). The upper and lower confidence limits are based on the product of the two random variables from tables produced by Meeker, Cornwell, and Aroian (1981). When the confidence intervals do not include zero, mediation is significant. As shown in Table 5, the confidence limits for mediation by the teacher–child relationship of the EC to academic competence (GPA and absences) relation do not include zero. Table 5 also indicates that the teacher–child relationship mediated 14% of the effect of EC on GPA and 40% of the effect of EC on absences.

Findings in the second panel of Table 4 demonstrate that EC was positively related to social competence and that social competence partially mediated the relation between EC and GPA but not absences (see Table 5 for the confidence limits and the percentage of variance that was mediated). In contrast, consistent with the findings for the teacher–child relationship, there was evidence that classroom participation partially mediated the relation be-

tween EC and GPA and mediated the relations between EC and absences (see the third column of betas in Table 4).

Although we did not expect findings to differ by ethnicity, we computed interactions to test if the strength of the relations differed for Mexican American versus European American students, because 47% of the sample was Mexican American and the next largest percentage of ethnic population represented was European American (30%). We added the main effect of ethnicity (i.e., Mexican American vs. European American) and the interaction of ethnicity and EC when predicting the teacher-child relationship, social competence, and classroom participation. When predicting GPA or absences, we also tested if the mediators interacted with ethnicity. None of the interaction terms or main effects of ethnicity were significant. The relatively small sample sizes for the other ethnic groups (e.g., African American students) precluded the

testing of further ethnic group comparisons. Thus, consistent with expectations, there was no evidence that the strength of the findings differed across the ethnicities we tested.

## Discussion

Our primary purpose in this study was to begin to fill a gap in the literature on the regulatory and social variables related to children's school success. Despite a recent research emphasis on the importance of academic functioning for positive developmental trajectories (Ladd, 2003; Welsh et al., 2001), 15% of U.S. students drop out of formal schooling prior to graduating from high school (Stoops, 2004). Students who perform poorly often develop negative attitudes and poor scholastic habits early in their school careers; thus, a better understanding of the regulatory and social factors that are related to academic achievement in early academic grades may inform intervention programs for these students. Therefore, our first goal was to test if EC was positively related to changes in children's grades and absences, and the second goal was to test if part of the relation between EC and academic competence was mediated by children's social relationships and classroom participation.

Results supported the hypothesis that EC was positively related to grades and negatively related to absences. This relation is consistent with limited theory and data (Eisenberg et al., 2005; Hill & Craft, 2003; Raver, 2002; Valiente et al., 2007). Blair (2002) has argued that EC, and particularly attentional regulation, is related to academic competence because students who have difficulty directing their attention and behavior likely experience significant challenges when trying to learn and focus on educational material. This explanation has roots in the cognitive literature (Ruff & Rothbart, 1996) and is supported by findings that children who have diffi-

Table 5  
Confidence Limits for Mediated Effects

Effect	Lower confidence limit	Upper confidence limit	Total effect that was mediated
EC > TCR > GPA	.01	.15	14%
EC > TCR > Absence	-.18	-.02	40%
EC > SC > GPA	.02	.18	19%
EC > SC > Absence	-.08	.07	1%
EC > PART > GPA	.12	.32	36%
EC > PART > Absence	-.29	-.08	76%

Note. EC = children's effortful control; TCR = teacher-child relationship; GPA = grade point average; SC = social competence; PART = classroom participation. Bolded effects are significant at the .05 level because the confidence limits do not contain zero.

culty with attention often have poor reading and language skills (McGee, Partridge, Williams, & Silva, 1991; Tamis-LeMonda & Bornstein, 1989), perhaps because frequently shifting attention and moving between tasks interfere with both learning and completing tasks.

Consistent with our hypotheses, there was evidence that some of the relation between EC and grades (as well as absences) was mediated by the teacher-child relationship, social competence (for grades only), and classroom participation. To our knowledge, this is the first study to find that the teacher-child relationship and social competence mediate part of the relation between EC and grades. A number of investigators have found links between children's EC and their social competence, problem behaviors, and social skills (see Rothbart & Bates, 2006, for a review), and data from this study suggest that part of the reason children high in EC perform well in school is indirect and through their social relationships at school. These results support the hypothesis that students' relationships in the school context are important for school success (Baumeister & Leary, 1995; Furrer & Skinner, 2003). It is also possible that when children are low in EC and disruptive in class, they receive less classroom support from teachers and peers, miss out on learning opportunities, and view the classroom environment negatively and as something to be avoided.

In addition to the teacher-child relationship and social competence, classroom participation partially mediated the relation between EC and GPA and mediated the relation between EC and absences. These results are consistent with findings that classroom participation is positively related to math and language skills (Buhs & Ladd, 2001) and improvements in academic achievement (Ladd, Buhs, & Seid, 2000) and with evidence that school liking mediates the relation between EC and academic competence (Valiente et al., 2007). The data presented here coincide with Wentzel's (1999) hypothesis that children who are comfortable and engaged at school may also perform well academically because they are motivated to pursue goals valued in the school context.

There is increasing evidence that indices of EC are related to students' academic competence. In this article, we have argued that part of the reason for this relation is that EC provides students with both relational and motivational advantages that help them perform well. Because we found evidence of partial mediation (especially for grades), there is some evidence that EC also has a direct effect on academic competence. Perhaps there are components of EC that are more closely tied to academic performance and that are independent of relational and motivational processes. In future work, it would be useful to measure various components of EC and related constructs to more closely assess why there are both direct and indirect effects. More cognitively oriented components of EC such as planning and attention allocation may be directly related to academic competence. Inhibitory components are necessary for desirable behavior, and these may be aspects of EC that are mediated by constructs such as social competence, the teacher-child relationship, and classroom participation. One could test the working hypothesis that social and motivational processes mediate the relational and inhibitory components of EC, but the attentional advantages directly relate to academic competence by obtaining purer measures of the components of EC. Advancing this approach is one way to more fully explain why preschoolers' ability to delay gratification is associated with later verbal and quantitative SAT scores (Shoda et al., 1990).

This study demonstrates several strengths. First, we incorporated data from multiple reporters for all variables (i.e., parents, teachers, and children reported on the same variables) to reduce common source variance. Second, although researchers have recently attended to the influence of EC on academic competence, few have examined processes or mechanisms underlying this relation. A more precise understanding of why relations emerge between EC and academic performance and school absence is useful for promoting children's positive development. Third, the inclusion of a large percentage of Mexican American participants strengthens this study: The U.S. Bureau of the Census (2004) reported that by 2050, 25% of students will be of Latino descent, yet research on the normative academic functioning of this population is rare. Understanding school success among ethnic minority students is particularly important because a robust association between ethnic minority status and the likelihood of failing to complete high school has been established, with Latino students ranked most likely to drop out (Kaufman, Alt, & Chapman, 2004; U.S. Bureau of the Census, 2004). In this study, results did not differ for the European American participants and the Mexican American participants.

Finally, although not all variables were assessed longitudinally, academic competence was examined at two time points. Prediction of children's academic competence in the spring was examined while controlling for their academic competence in the fall. By controlling for fall grades or absences when examining regulatory and social contributors to children's spring grades or absences, one can assess how these factors related to academic competence beyond children's preexisting academic ability.

Despite strengths, this study had some limitations. First, we used concurrent assessments of children's EC, social competence, and classroom participation. Our data are thus correlational and do not allow for firm conclusions about directionality. Second, although the scores used in this study are valid and relate to observed indices of the relevant constructs (Birch & Ladd, 1997; Capaldi & Rothbart, 1992; Eisenberg et al., 2000), the data in the current study were assessed with questionnaires only, and future studies would benefit from using observational assessments. For example, Kochanska and colleagues have developed a battery of tasks to measure young children's EC, and methods are available to observationally code both student-teacher interactions and engagement (Kochanska et al., 2000, 2001; Ladd et al., 1999; Pianta, La Paro, Payne, Cox, & Bradley, 2002). These methods will be especially useful tools to elaborate on the beginning stages from this line of research. Finally, this line of research would be strengthened by adding a measure of IQ to the models. Evidence indicates that measures of children's regulatory abilities, relationships, and participation relate to academic competence beyond the effects of IQ (Blair, 2001; Gottfried, 1990; Masten et al., 2005), but it remains possible that the strength of the relations would be reduced after including IQ.

Despite these limitations, the findings from the current study advance the understanding of the relations between regulatory and social variables and academic competence and provide new information about mechanisms that may explain why children's regulatory abilities are associated with their learning and school success. The results presented here provide evidence that EC is related to academic competence, that the teacher-child relationship and classroom participation partially mediate the relation of EC to

GPA and absences, and that social competence partially mediates the relation of EC to GPA. These models present some possible process mechanisms underlying factors that are associated with children's academic competence, and these findings emphasize the importance of considering regulatory and social influences on academic competence in future models.

# A Multilevel Perspective on Gender in Classroom Motivation and Climate: Potential Benefits of Male Teachers for Boys?

Herbert W. Marsh  
University of Oxford

Andrew J. Martin  
University of Sydney

Jacqueline H. S. Cheng  
University of Oxford

Are boys better motivated by male than female teachers in high school math, science, and English classes, and can these differences be explained by classroom climate? Using a cross-classified multilevel model with 5 levels (school, teacher, class, student, subject), the authors found little or no support for this contention. In general (except in terms of anxiety and persistence), girls were better motivated than boys, and these differences tended to generalize over student age and school subject in classes taught by both male and female teachers. Student perceptions of classroom climate were more specific to the group of students within a particular class than to the teacher who taught the class and had moderate to large effects on the motivation of individual students. The surprisingly small amounts of variance explained in motivation by student gender and age, teacher gender, school subject, and their interactions support a gender invariance and similarities model but not theoretical predictions based on gender stereotype, gender intensification, and gender matching perspectives.

**Keywords:** student and teacher gender, student motivation, classroom climate, multilevel modeling with cross-classification

Do boys fare better in classes taught by male teachers? In a recent article in the *Washington Post* newspaper, columnist Ben Feller (2006) stated, "For all the differences between the sexes, here's one that might stir up debate in the teacher's lounge: Boys learn more from men and girls learn more from women." He then went on to describe research in support of this claim by Dee (2006) that has attracted media publicity across the United States. Included in his article was an array of quotes in support for and against the basic contention that boys are benefited by male teachers. Clearly, the debate on this topic is not limited to the United States, as an Australian Labor Party (the major opposition political party at the time) policy document leading up to a recent federal election stated, "Now, more than ever, young boys need contact with men who can offer positive role models and mentor them in the right direction (p. 1). . . . Labor wants to see many more male teachers teaching and making a difference to the lives

of young boys in our schools" (Australian Labor Party, 2004, p. 4). In contrast, on the basis of interviews with teachers in Iceland, Jóhannesson (2004) was especially critical of the "myth that boys in particular need 'male role models'" (p. 33). Weaver-Hightower (2003) reviewed the political, research, and practice-oriented causes of the recent upsurge in interest in boys' education and what he called the "boy turn," which has focused on the schooling experiences and outcomes of boys.

Following from this controversy, which bridges popular media, academic research, and policy development all over the world, the focus of this study is the question, "Are boys better motivated by male teachers?" In addressing this issue it is, of course, critical to evaluate motivation for both male and female students who are taught by male and female teachers. Hence, whereas our focus is on motivating boys as the starting point for our research, the results have implications for girls as well. In pursuing an answer to our question, we begin by briefly reviewing theoretical and empirical research on gender differences, consider how teacher gender and student gender might interact (the matching hypothesis), and apply new statistical procedures—cross-classified multilevel modeling (MLM)—that are ideally suited to exploring interactions between student gender and teacher gender.

Addressing teacher effects on student motivation also provides an opportunity to explore other important and cognate issues, particularly under a multilevel framework such as that developed here. Thus, for example, we argue that to the extent that teachers affect the motivation levels of their students, these effects are likely to be mediated at least in part by classroom climate. Hence, while addressing teacher effects, we are also able to assess—using appropriate analytic methods—the role of class climate in student

---

Herbert W. Marsh and Jacqueline H. S. Cheng, Department of Education, University of Oxford, Oxford, England; Andrew J. Martin, Faculty of Education and Social Work, University of Sydney, Sydney, Australia.

Work on the present investigation was conducted, in part, during the periods when each of us was part of the SELF Research Centre at the University of Western Sydney and while Andrew J. Martin was Visiting Research Fellow at the University of Oxford. This research was supported in part by a grant from the Australian Research Council.

Martin, Faculty of Education and Social Work, University of Sydney, Sydney NSW 2006, Australia. E-mail: herb.marsh@education.ox.ac.uk or a.martin@edfac.usyd.edu.au

motivation and attempt to disentangle the respective roles of teacher and class composition in shaping student motivation and classroom climates, which are posited to be one basis of motivation in individual students. In this respect, the present investigation is a methodological–substantive synergy (Marsh & Hau, 2007) involving new and evolving statistical analyses—in this case, MLM—that allow us to evaluate substantive issues that could not easily or appropriately be pursued without such advances. Hence, this study addresses important substantive issues that are not effectively evaluated with existing statistical procedures, thereby providing a catalyst for the development of better methodology.

### The Gender Invariance Hypothesis and the Matching Hypothesis

In education research and policy—indeed, in the psychological and social science disciplines more generally—there is a preoccupation with gender differences (see Hyde, 2005). Fueled in part by a null hypothesis testing perspective, given a sufficiently large sample size, there will be statistically significant gender differences for most psychosocial variables. However, this focus on gender differences tends to ignore the strong support for gender similarities and the typically small sizes of gender differences. As emphasized by Hyde (2005) in her meta-analytic review of meta-analyses of gender differences, men and women are more similar than different on most variables. She argued that overinflated interpretations of small gender differences can do much harm and lead to counterproductive policies. In education in particular, there is a long history of research about the effect of the gender of both students and teachers. In this article, we test a matching hypothesis, coupled with gender stereotype and gender intensification models, about how gender differences in student motivation in different school subjects are influenced by the gender of the teacher.

Marsh (1989a, 1989b) reviewed research into gender differences, particularly that by Eccles and colleagues (e.g., Eccles, 1987; also see Eccles & Wigfield, 2002), and into differential socialization processes proposed by many other researchers (e.g., Maccoby & Jacklin, 1974). He posited and tested a differential socialization hypothesis in which “sex-linked differences in socialization patterns may fail to reinforce adequately boys’ positive attitudes, expectations, and performance in verbal areas as well as failing to reinforce adequately girls’ positive attitudes, expectations, self-concepts, and performance in mathematics” (Marsh, 1989b, p. 195). Although he found small gender-stereotypic differences for math and verbal constructs that were consistent with other research (e.g., Hyde, 2005), he also identified a more long-term perspective based on nationally representative samples showing that gender differences favoring girls were becoming larger, whereas gender differences favoring boys were becoming smaller (also see Martin & Marsh, 2005). Indeed, this trend of increasingly poorer academic outcomes for boys has fueled, in part, the question of whether boys are benefited by having male teachers. However, Marsh (1989b) found that other aspects of the gender-stereotypic model were not supported—relations among variables were largely invariant over gender.

Marsh (1993) provided an alternative test of the differential socialization model, in which it was predicted that English self-concept would be more highly related to academic and general

self-concept for girls, math self-concept would be more highly related to academic and general self-concept for boys, and these gender differences would grow larger with age. These predictions were consistent with Eccles’s (1987) finding that gender differences in the value placed on math and verbal competence grew larger with age and with what Hill and Lynch (1983) called gender-role intensification, in which conformity to gender-role stereotypes becomes increasingly important with age. However, Marsh (1993) found no support for these predictions, as relations were similar across eight groups (2 gender  $\times$  4 adolescent age groups). On the basis of his research, Marsh (1993; Marsh, Hau, Sung, & Yu, 2007; Marsh, Trautwein, Lüdtke, Köller, & Baumert, 2005; Martin & Marsh, 2005) argued for a gender-invariant model in which relations among gender-stereotypic constructs considered in his research were similar for boys and girls, a conclusion consistent with the gender similarities hypothesis posited by Hyde (2005).

In the present article, we extend this previous research to include a matching hypothesis in which student gender and teacher gender are hypothesized to interact—favorably when student and teacher genders match, but unfavorably when they do not. Previous research has sometimes tested a matching hypothesis as a potential source of bias. Thus, for example, Jayasinghe, Marsh, and Bond (2001, 2002) tested a matching hypothesis that peer reviews of grant applications would be higher when individual characteristics of the external assessor (e.g., gender, age, academic rank, status and type of institution) matched those of the applicant. However, in their MLM analysis covering all major science disciplines, they found no support for a matching hypothesis—operationalized in terms of statistically significant interactions between characteristics of the assessor and the applicant. In particular, there was no evidence that female (or male) reviewers gave systematically higher or lower ratings to proposals authored by female (or male) researchers.

In another application of the matching hypothesis, Marsh (1987b, 2007b) evaluated whether university students gave higher ratings of teaching effectiveness to same-gender teachers than to opposite-gender teachers. Support for such a matching hypothesis might imply a form of gender bias in the teacher evaluations or, alternatively, the claim that men are more effective teachers for male students, whereas women are more effective teachers of female students. However, Marsh argued that there was little or no support for a matching hypothesis—and, by implication, either of these alternative interpretations (also see Feldman, 1992, 1993). Although Centra and Gaubatz (2000) found some support for a matching hypothesis on the basis of students’ evaluations of university teaching, he emphasized that the sizes of the effects were too small to be substantively important.

In the present investigation, we combine theoretical perspectives from gender-stereotypic, gender intensification, and matching perspectives with new developments in MLM to test whether boys are better motivated by male teachers. Inherent in any discussion of the teacher effects on the motivation levels of individual students within a classroom is the motivational orientations within the classroom—the classroom climate. Hence, teacher effects on student motivation—and their interaction with other student characteristics, such as student gender—are likely to be mediated, at least in part, by classroom climate. Here we bring together the study of individual student motivation, student and teacher gender,

and classroom climate within an appropriate MLM framework that is ideally suited to this purpose and demonstrate the new applications of this important statistical procedure, which we now discuss in greater detail.

### The Hierarchical Nature of Motivation and Classroom Climate: An MLM Approach

Our intent is to apply important advances in the application of MLM (also referred to as *hierarchical linear modeling*) to the study of motivation, teacher effects, and classroom motivation climates (also see Ntoumanis & Vazou, 2005; Papaioannou, Marsh, & Theodorakis, 2004; Raudenbush, Rowan, & Kang, 1991). Particularly in education—and the social sciences more generally—data typically have a multilevel structure in which individuals are clustered into groups (e.g., classes), which might be clustered into higher level administrative units (e.g., schools). Individual student characteristics and those of the classes to which students belong are usually confounded because individuals are not randomly assigned. Students are typically more similar to other students within their class than they are to other students from different classes.

When data have a multilevel structure, single-level analyses that ignore this multilevel structure are typically invalid (violating statistical assumptions in a way that increases the likelihood of a Type I error; for further discussion, see Goldstein, 2003; Raudenbush & Bryk, 2002). Although these statistical issues dictate that MLM analyses should be used routinely, a substantive MLM focus opens up important new perspectives about how constructs operate at the individual and group levels. However, an MLM perspective also provides new challenges for theory, research, measurement, and practice. Thus, for example, the same construct measured at the level of the individual and at the level of the group may lead to fundamentally different interpretations (e.g., Marsh & Hau, 2003). Furthermore, measures that have good psychometric properties at the individual level may not be satisfactory at the group level (e.g., Marsh, Rowe, & Martin, 2002). Hence, measures demonstrated to be effective at one level must also be evaluated at other levels to which they are applied via a traditional construct validity approach. In addition, there may be substantively important questions of practical significance that involve interactions between individual- and group-level variables. For example, in the present investigation we posit a matching hypothesis in which boys are better motivated by male teachers. An evaluation of interactions between variables at the individual student level and the teacher level is inherently an MLM issue. Hence, the MLM method provides a much richer and more appropriate methodological approach to evaluating motivational climate than would be possible with traditional single-level approaches, which ignore the clustering of individuals within groups.

Particularly when the focus of the research is on an inherently class-level variable, such as climate, it makes no sense to ignore the class level in the analysis. Traditionally, researchers have distinguished between the motivational levels of individual students and the perceptions of the individual students about the classroom motivational climate. Although the motivational levels of individual students are clearly designed to be an individual-level variable, the appropriate level of analysis for classroom climate is not straightforward. Historically, individual student perceptions of

classroom climate have typically been analyzed with single-level analyses that treat classroom climate as an individual student-level variable (e.g., Ames, 1992; Ames & Archer, 1988; Levesque, Zuehlke, Stanek, & Ryan, 2004; Papaioannou, 1995; Seifriz, Duda, & Chi, 1992). In contrast, we argue that classroom climate is inherently a class-level construct. When climate measures are based on responses about the overall class climate by a single person for each class (e.g., teacher or external observer), then it is clear that the level of analysis is the class. When each student in a class evaluates the classroom climate, it is possible to consider responses at both the individual and the classroom levels. Even here, however, we argue that the most appropriate measures of the classroom climate are aggregates of individual student perceptions. It is, however, important to evaluate classroom perceptions of individual students as well. If, for example, there is little or no agreement about classroom climate among students within the same class, then support for the construct validity of the perceived climate ratings is dubious (in the same way as lack of agreement among items designed to measure the same construct undermines support for the construct validity of the construct). This is not to say, of course, that the perceptions of each student and how these individual student perceptions differ from the aggregated perceptions are not also important. Fortunately, recent advances in MLM provide new opportunities to combine constructs from different levels of analysis. Hence, the issue is not whether research should be done at the level of the individual participant or the group level but how best to combine measures from multiple levels of measurement.

In classroom climate research, classroom climate is often posited to be a function of the teacher who teaches a class. However, as is the case with all teacher effects, a viable alternative is that classroom climate is a function, at least in part, of the students who compose the class. Typically, the effects of a teacher and the class are completely confounded and cannot be distinguished. However, when the design of an appropriate MLM study contains more than one class per teacher, it is possible to distinguish between these alternative explanations, evaluating the extent to which effects of a given teacher generalize over different classes taught by the same teacher. This distinction is particularly important in studies such as ours, in which we are specifically concerned with the generalizability of effects associated with characteristics of different teachers (i.e., teacher gender).

### Substantive Hypotheses and Research Questions

The present study encompasses substantive questions regarding the effects of teacher gender on student motivation and the differential levels at which variation in motivation occurs (e.g., student, class, teacher, and school levels). However, these issues also enable new methodological questions to be explored, such as the appropriate means by which to disentangle teacher and class composition effects and, in particular, the role of cross-classification analysis to achieve this. Hence, the present study, using cross-classification MLM, explores (a) the extent to which student gender, teacher gender, and their interaction impact on dependent variables consisting of multiple dimensions of student motivation, affective outcomes, and corresponding student perceptions of classroom climate and (b) the extent to which motivation, outcomes, and classroom climate perceptions vary as a function of

school subject, student, class, teacher, and school levels. To provide a substantive focus for our MLM analyses, we offer the following hypotheses and research questions adapted for the purposes of the present investigation from gender-stereotypic and gender intensification models and from the matching hypothesis. Consistent with concerns about boys increasingly falling behind girls in a variety of educational outcomes, which is an underlying theme driving the present investigation, we expected girls to be generally better motivated than boys (i.e., higher for adaptive motivations and outcomes, lower for maladaptive motivations). However, our focus is on how such gender differences vary as a function of the gender of the teacher, school subject, age, and that particular component of motivation. On the basis of our review, we propose the following research hypotheses and questions.

### *Gender-Stereotypic Differences and Gender Intensification*

Motivation, outcomes, and perceptions of classroom climate will be more favorable (i.e., higher for adaptive motivations and outcomes, lower for maladaptive motivations) in gender-stereotypic subjects (i.e., more favorable for girls in English and for boys in math and science). Gender-stereotypic differences in motivation will grow larger with age as students move into adolescence.

### *Matching Hypothesis*

Boys, in particular, will be more motivated by male teachers than by female teachers, but girls will also be more motivated by female teachers. In support of the gender intensification hypothesis, this Student Gender  $\times$  Teacher Gender interaction is predicted to become stronger with age.

We leave as a research question whether support for the matching hypothesis varies as a function of the school subject. It could be argued that effects of student-teacher gender matching are particularly large in subjects that go against traditional gender stereotypes (positive effects of male English teachers for boys and of female math and science teachers for girls), where motivation is more likely to be lower. Alternatively, it could be argued that male teachers are particularly able to motivate boys in math and sciences, whereas female teachers are particularly able to motivate girls in English classes.

### *Gender Invariance and Similarities Model*

In contrast to predictions based on gender stereotypes and the matching hypothesis, this model predicts that gender differences in motivation and classroom climate tend to be small (gender similarities) and do not vary much with school subject, age, or gender of the teacher (gender invariance). Support for the gender similarities prediction comes from Hyde (2005), whereas empirical and theoretical support for the invariance hypothesis is from Marsh (1993; Marsh et al., 2005, 2007; Martin & Marsh, 2005). However, it is important to emphasize that there is apparently very little rigorous empirical support for either the matching hypothesis (that boys are better motivated by men and girls are better motivated by women) or the invariance hypothesis (that teacher gender and student gender do not interact). Nevertheless, we contend that

there is sufficient justification for the invariance hypothesis to warrant positing it as a specific hypothesis to be tested. In particular, although it could be argued that the invariance hypothesis is implicit in the matching hypothesis (i.e., it is the null hypothesis in tests of Student Gender  $\times$  Teacher Gender interactions), we chose to make it explicit as a viable alternative hypothesis. Whereas arguing for the null hypothesis is always a precarious undertaking, the juxtaposition of competing sets of hypotheses involves a critical evaluation of the practical implications of the direction and sizes of effects.

A second important component of our research is classroom climate at the levels of student, class, and teacher and how it affects student motivation. In part, our research builds on earlier research by Papaioannou et al. (2004) that evaluated classroom motivational climates in physical education classes. They found that teacher effects were very small for individual student motivation but, not surprisingly, were larger for classroom motivational climate. Furthermore, the motivational climates in these physical education classes were more a function of the teachers who taught the class than of the particular group of students who were in the class—motivation climates associated with a particular teacher tended to generalize across different classes taught by the same teacher. Here we evaluate how these results generalize to mathematics, English, and science classes and the implications of these results to gender differences associated with student and teacher gender.

### *Motivation and Climate at the Level of the Student, Class, and Teacher*

There are distinguishable effects in classroom climates associated with the teacher who teaches a class (teacher-level effects) and the particular group of students in a specific class (class-level effects). While we expect that there are teacher-level effects that generalize across the different classes teachers teach, there may also be class-level effects that are idiosyncratic to particular groups of students and that do not generalize to other classes taught by the same teacher (e.g., Papaioannou et al., 2004). There is a strong body of research at the university level showing that students' evaluations of effective teaching are primarily a function of the teacher who teaches a class rather than of the class or group of students who rate a particular class (Marsh, 1987b, 2007b). However, because there is little research on this issue at the primary or secondary level that focuses on motivation and classroom climate, we posit this as a research question to be explored.

Effects of teachers and classrooms are stronger for student perceptions of classroom climate than for the corresponding measures of individual student motivation and outcomes (e.g., Papaioannou et al., 2004). Conversely, it follows that individual student effects should be stronger for student motivation than for classroom climate perceptions (e.g., Papaioannou et al., 2004). Taken together, these two predictions imply that perceptions of classroom climate should be more specific to particular classes and teachers, whereas motivation levels of individual students should be more specific to individual students. This set of hypotheses merely means that there should be better agreement among students within the same class when they rate the class in terms of classroom climate than when they rate their own individual levels of motivation. Indeed, failure to support this commonsense hy-

pothesis would call into question the construct validity of the classroom climate ratings. The critical aspect of this prediction is that there should be substantial agreement among students within the same class in terms of their classroom climate ratings. To better understand this prediction, it may be useful to consider a somewhat analogous situation for items (analogous to different students within the same class) and factors (analogous to the different classes). The analogous prediction from the item-factor perspective is that items designed to measure the same factor should be more highly correlated with each other than with items designed to measure a different factor. Similarly, students who are making ratings of the same classroom should show greater agreement among each other than with other students who are rating a different classroom.

Individual motivation levels for the same student do generalize over different school subjects. Research by Marsh, Martin, and Debus (2001) suggests that for motivation constructs such as those measured here, there is substantial agreement in motivation levels across math and verbal subjects, although there are some self-belief constructs in which the relation is close to zero (i.e., math and verbal self-concepts; Marsh, 2007a). Hence, we expect that the student effect—the extent to which motivation varies across different school subjects—will be substantial for individual ratings of motivation but that its size should vary across different motivation constructs.

To what extent does classroom climate—at the level of the classroom—have a substantial influence on individual student motivation? To what extent are classroom and teacher effects on individual student motivation mediated by classroom climate? While these are critical research questions, there is not sufficient research from an MLM perspective (which we argue is necessary to address this issue) to make a priori predictions. However, an affirmative response to these questions would provide support for the construct validity of climate ratings.

## Method

### *Sample and Procedure*

The present study focuses on Year 8 and 10 high school students in their mathematics, English, and science classes. The sample comprises 964 high school students from five Australian coeducational government schools: 60% in Year 8 (junior high school, mostly 12 and 13 years of age), and 40% in Year 10 (middle high school, mostly 15 and 16 years of age). Nearly half (48%) the respondents were girls, and 52% were boys. The mean age was 14.30 ( $SD = 1.12$ ) years. In total, 101 classrooms, taught by a total of 62 teachers (58% female), were surveyed.

Teachers administered the Motivation and Engagement Scale—High School (MES-HS; Martin, 2001, 2003d, 2006a, 2007) as well as affective outcomes of relevance. In addition, they completed single-item classroom climate scales designed to parallel the motivation and outcome scales. The rating scale was first explained, and a sample item was presented. Students were then asked to complete the instrument on their own and to return the completed instrument to the teacher at the end of class. It is important to note that students rated their motivation and engagement in the corresponding class (i.e., mathematics motivation was evaluated in math classes, English motivation in English classes,

and science motivation in science classes). Students completed the math survey in a mathematics class ( $n = 964$ ), and most completed either an English survey in their English class ( $n = 331$ ) or a science survey in their science class ( $n = 406$ ).

### *Materials*

Materials considered here were based on responses to the MES-HS (Martin, 2001, 2003d, 2006b, 2007), other affective outcomes constructs deemed to be of relevance to the breadth of students' experience in the classroom, and corresponding measures of classroom climate (see Martin, 2007, for a full description of the development and origins of MES-HS scales). The MES-HS assesses six adaptive motivation scales (three cognitive and three behavioral) and five maladaptive motivation scales (three cognitive and two behavioral). Each of the 11 factors comprises 4 items—44 items in all. To each item, students rate themselves on a scale of 1 (*strongly disagree*) to 7 (*strongly agree*). Previous results (Green, Martin, & Marsh, 2006; Martin & Marsh, 2005; also see Martin, 2001, 2003d, 2007; Martin & Marsh, 2006) provided strong psychometric support for the factor structure of the instrument. A 16-factor confirmatory factor analysis based on the 44-item (11-factor) MES-HS items and the additional 20 items assessing each of the five additional affective outcomes yielded an excellent fit to the data (nonnormed fit index = .97; comparative fit index = .97; root-mean-square error of approximation = .047). Factor loadings relating each item to its a priori factor were consistently substantial, and reliability (coefficient alpha) estimates for the 16 scales (varying from .74 to .89) were good given the brevity of the 4-item factors. Martin (2001, 2003d, 2007) also showed that the MES-HS has a sound factor structure; comprises reliable and approximately normally distributed dimensions; and is significantly associated with literacy, numeracy, and achievement in mathematics and English.

*Adaptive dimensions of motivation and engagement.* Each adaptive dimension fell into one of two groups: cognitions and behaviors. Adaptive cognitions included self-efficacy, mastery orientation, and valuing. Adaptive behaviors included persistence, planning, and task management. In terms of adaptive cognitions, *self-efficacy* (e.g., "If I try hard, I believe I can do my schoolwork well") is students' belief and confidence in their ability to understand or to do well in their schoolwork or studies, to meet challenges they face, and to perform to the best of their ability. *Valuing* (e.g., "Learning at school is important") is how much students believe what they do and learn at school is useful, important, and relevant to them or to the world in general. *Mastery orientation* (e.g., "I feel very pleased with myself when I really understand what I'm taught at school") entails being focused on learning for the development of mastery, competence, and success by dint of and as reflective of effort and skill development.

In terms of adaptive behaviors, *planning* (e.g., "Before I start an assignment, I plan out how I am going to do it") refers to how much students plan their schoolwork and projects and how much they keep track of their progress as they are doing that work. *Task management* (e.g., "When I study, I usually study in places where I can concentrate") refers to the way students use their time, organize themselves, and choose and arrange where they do their schoolwork and study. *Persistence* (e.g., "If I can't understand my schoolwork at first, I keep going over it until I do") is how much

students keep trying to work out an answer or to understand a problem even when that problem is difficult or challenging.

*Maladaptive dimensions of motivation and engagement.* Each maladaptive dimension fell into one of two groups: cognitions and behaviors. Maladaptive cognitive dimensions were anxiety, failure avoidance, and uncertain control. *Anxiety* (e.g., "When exams and assignments are coming up, I worry a lot") had two parts: feeling nervous and worrying. Feeling nervous is the uneasy or sick feeling students get when they think about their schoolwork, assignments, or tests. Worrying is their fear of not doing very well in their schoolwork, assignments, or tests. *Failure avoidance* (e.g., "Often the main reason I work at school is because I don't want to disappoint my parents") reflects an orientation whereby the main reason students try at school is to avoid doing poorly, being seen to do poorly, or the negative consequences of doing poorly. *Uncertain control* (e.g., "When I get a bad mark I'm often unsure how I'm going to avoid getting that mark again") assesses students' uncertainty about how to do well or how to avoid doing poorly.

Maladaptive behavioral dimensions were self-handicapping and disengagement. *Self-handicapping* (e.g., "I sometimes don't study very hard before exams so I have an excuse if I don't do as well as I hoped") assesses an orientation whereby students do things that reduce their chances of success at school in an attempt to deflect the cause of possible poor performance away from a perceived lack of ability or competence. Examples are putting off doing a project or wasting time while they are meant to be doing their schoolwork or preparing for an upcoming assignment or test. *Disengagement* (e.g., "I've pretty much given up being involved in things at school") reflects an orientation whereby students feel like giving up in particular school activities or at school more generally. Students high in disengagement tend to accept failure and behave in ways that reflect helplessness.

*Affective outcomes.* To conduct a more expansive analysis of the issues under focus, we were also interested in exploring the nature of effects on some other conceptually relevant educational constructs. To this end, the sample was also administered multi-item scales that explored their enjoyment of the subject (e.g., "I enjoy this subject"), class participation (e.g., "I get involved in things we do in class"), educational aspirations (e.g., "I'd like to continue studying or training in this subject after I complete school"), teacher-student relationships (e.g., "I get along well with my teacher"), and academic resilience (e.g., "I think I'm good at dealing with schoolwork pressures"). Psychometric properties of these scales are presented below.

*Classroom climate.* For each of the 16 motivation and affective outcome scales, students also made a parallel rating on a single-item scale designed to assess classroom climate. Each of these items began with the phrase "In this class, students . . ." (e.g., "In this class, students believe that they can do a good job on their schoolwork," "In this class, students enjoy this subject," "In this class, students are quite anxious about schoolwork and tests," and "In this class, students have a good relationship with the teacher"), and students responded on the same 7-point response scale as for the other items. It is important to note that while ratings of the 16 motivation and outcome scales were in relation to the individual student completing the survey, the classroom climate ratings were generalized ratings of perceptions about students from the same class as a whole.

### Statistical Analysis: MLM

*Cross-classification.* In traditional MLM, units have a purely hierarchical or nested structure in which units at a lower level (e.g., students) occur at only one level of a higher order unit (e.g., schools). In cross-classified analyses, however, a unit may be classified along more than one dimension (Browne, 2005; Goldstein, 2003; Raudenbush & Bryk, 2002; Snijders & Bosker, 1999). Typical applications include, for example, students classified by their school and neighborhood when students from the same neighborhood attend different schools (i.e., neighborhoods are not nested under schools). Failure to account for such cross-classification can substantially bias estimates of variance explained by the different levels. In the present study, classes were nested under teachers (each class was taught by only one teacher), and teachers were nested under schools. Although each combination of student and subject was nested under class, student and subject were cross-classified. Because students had data for different subjects, the data structure was a cross-classified structure rather than a multiple membership model. While cross-classified analyses have not been handled easily by MLM statistical packages until recently, they are facilitated by recent developments in MLMs (see Browne, 2005, for further discussion of the Markov chain Monte Carlo estimation procedures implemented in Version 2 of MLwiN), providing a much stronger statistical basis for testing substantive research hypotheses and questions raised in the present investigation.

*MLM design of the present investigation.* For purposes of the present investigation, the data were conceptualized as a five-level cross-classified MLM (levels were school, teacher, class, student, and subject). The MLM analyses were conducted with MLwiN Version 2.02, with Markov chain Monte Carlo estimation used for cross-classified models (Browne, 2005; also see Rasbash, Steele, Browne, & Prosser, 2004). Classes were nested under teachers, teachers were nested under schools, and each combination of student and subject was nested under class. However, student and subject were cross-classified. In preliminary analyses, a baseline variance components model (Rasbash et al., 2004) or intercept-only model (Hox, 1995) was used to evaluate how much variation in each of the dependent measures (motivation, affective outcomes, classroom climate perceptions) could be attributed to each level. Following variance components models, the major focus of analyses was on a set of MLM path models to test the effects of student and teacher gender, subject (math, English, and science), grade (8th and 10th grade), and their interactions on various dependent variables.

Several data transformations were used to facilitate interpretations and infer interaction effects. We standardized ( $z$  scored) all independent and dependent variables to have  $M = 0$  and  $SD = 1$  across the entire sample (Marsh & Rowe, 1996; also see Aiken & West, 1991; Raudenbush & Bryk, 2002). Product terms were used to test interaction effects. In constructing these interaction effects, we used the product of individual ( $z$  score) standardized variables, but product terms were not restandardized (i.e., were left in the metric of variables composing the product terms).

In MLM studies, the individual is typically taken to be the lowest level (e.g., students nested within classes, classes nested within teachers, teachers nested within schools). In this case, variance associated with individuals is part of the residual variance

term, so that variance specifically associated with differences between individuals cannot be differentiated from other, idiosyncratic sources of variance that contribute to the residual variance term. However, it is possible to introduce additional levels that are nested under individuals. Thus, for example, in longitudinal studies, occasions are nested under individuals, so that individual-level variance indicates how well responses by the same individual generalize over time. In the present investigation, we introduced school subject (math, English, science) as an additional level and evaluated the extent to which motivational levels and classroom climate perceptions of the same student generalized across different school subjects. In particular, we posited that individual student motivation should generalize over subjects to a much greater extent than for the corresponding measures of classroom climate.

Another interesting feature of our MLM design is that many teachers taught more than one class within the same subject area (math, English, and science). Typically, when there are data for only one class for each teacher, the effects of the teacher and the group of students within this class are completely confounded; there is no basis for determining the extent to which teacher effects generalize over different classes taught by the same teacher. In the present investigation, however, class—the group of students within the class—was nested under teacher, so that it is possible to determine the extent to which effects were specific to one group of

students or generalized across different classes taught by the same teacher.

Results

Preliminary (Single-Level) Analyses

We began with preliminary, single-level analyses to provide a descriptive (nonstatistical) overview of the results before moving to the more complicated cross-classified MLM analyses. Because these single-level analyses ignore the complicated multilevel structure of the data, tests of statistical significance for these results are biased and so are not discussed. In Figure 1 we present box-plot graphs for each of the 11 motivation scales as a function of student gender, teacher gender, and school subject—keeping in mind that the first 6 (of 11) scales were positively oriented, adaptive motivational constructs, whereas the last 5 were negatively oriented, maladaptive motivational constructs. For all 6 positively oriented motivations, girls tended to have higher motivations than boys, and this trend appeared to generalize over classes taught by male and female teachers. For negatively oriented motivations, gender differences appeared to be small—except for anxiety, for which girls were more anxious than boys. Again, however, these gender differences (or lack thereof) tended to be similar for male and female

Figure 1. Box plots of 11 motivation scales for each of three school subjects, presented separately as a function of student and teacher gender. Box plots represent the median (dark line within each box) and the 25th and 75th percentiles (the boxes). The 11 motivation scales (in order of presentation) were Efficacy, Value, Mastery, Plan, Manage, Persist, Anxiety, Uncertain Control, Avoid, Handicapping, and Disengage.

teachers. Hence, these preliminary analyses do not seem to provide either support for gender-stereotypic differences in motivation in different school subjects or support for the matching hypothesis that boys are better motivated by male teachers, but these analyses seem to support the gender invariance and similarities model.

### *Cross-Classified Multilevel Analyses*

To more appropriately evaluate relations between independent variables (student gender, teacher gender, year in school, school subject, and all their interactions—represented by a set of 23 dummy variables) and dependent variables (adaptive motivations, maladaptive motivations, affective outcomes, and corresponding perceptions of classroom climate), we estimated a series of cross-classified models for each dependent variable. The effects of the entire set of predictor variables were estimated for individual students' ratings of their own motivation (Model 1; see Tables 1, 2, and 3) and their perceptions of the classroom climate. In preliminary analyses, variance component models (with no independent predictor variables, sometimes referred to as "null" models) were estimated separately for individual student ratings of their own motivation (the null model corresponding to Model 1 [M1o]) and their corresponding classroom climate perceptions (M2o). Finally, in Model 3, we added the class average of classroom climate ratings to Model 1 to determine how much of the variance in individual student motivation levels could be explained in terms of a generalized perception of classroom climate and how the inclusion of the class-average climate ratings influenced other fixed and random effects. Because of the complicated nature of these results, we present the results for self-efficacy (see Table 1) in detail and then summarize the key findings for other dependent variables.

**Self-efficacy.** Variance components for student self-efficacy (M1o; see the bottom of the first column in Table 1 under the heading *Efficacy*, labeled *Variance components*) show that variance components associated with the school, the teacher, and the classroom were all nonsignificant. This means the differences in efficacy did not differ significantly as a function of school, the teacher, or the classroom. The largest variance component (.573) was for the individual students. The means that a majority of the variance in self-efficacy ratings—approximately 57%—was due to differences between students. This is substantively important in that it shows that self-efficacy ratings by the same student generalized reasonably well over different (math, English, and science) subjects. As is typical in most psychosocial research, the residual variance component (which includes differences between subjects as well as a potentially infinite number of other sources of variance) was also statistically significant. Taken together, results of this variance components model (with no predictor variables) suggest that student self-efficacy was largely a function of the individual student and not the school they attended, their teacher, or the group of students in their class.

The pattern of results for variance components associated with self-efficacy classroom climate (M2o) was very different. Whereas variance components associated with school and teacher were not statistically significant, the variance component for classroom was significant. Although the variance component associated with individual students was still statistically significant, it was much smaller than was the case of students' ratings of their own self-

efficacy. For classroom climate perceptions, the largest variance component (.713) was the residual variance term that included differences associated with different subjects.

The juxtaposition between M1o and M2o supports the construct validity of the classroom climate perceptions. While self-efficacy of individual students should be largely a function of the individual student, classroom climate perceptions should be a function of the classroom and teacher rather than the individual student (see the earlier discussion). The results support these expectations. Individual student self-efficacies generalized over subjects, whereas classroom climate perceptions of self-efficacy did not. Although the variance component associated with the class was not large, it should be noted that the reliability of the aggregated class-average perception of climate was a function of the variance component and the number of students in the class. Hence, a modest variance component associated with class can result in a reasonably reliable measure of classroom climate when based on responses from a sufficient number of students. It is important to note, however, that the classroom climate did not appear to be a function of the teacher—only the group of other students in the classroom. Hence, the classroom climate associated with a particular class did not generalize to other classes taught by the same teacher.

In Model 1, individual student self-efficacies were related to a set of 23 dummy variables representing the 4 independent variables: student gender (boy, a z-scored dummy variable in which positive values reflected higher scores for boys), teacher gender (male), year in school (Year 10), subject (math and science, with English as the "left out" level in the traditional set of dummy variables) and all possible interactions (see Table 1). Only 2 of 23 effects were statistically significant, and each of these was small. Girls had higher self-efficacies (averaged across the three subjects), but the difference was not large (approximately .09 standard deviations, as all the variables were standardized to facilitate interpretations). There was also a three-way interaction between year, student gender, and teacher gender. Supplemental analyses showed that whereas both boys and girls had higher self-efficacies when taught by women than men in Year 10, in Year 8 girls had similar self-efficacies in classes taught by men and women but boys had substantially higher self-efficacies for classes taught by women than for those taught by men. Hence, the nature of this interaction does not support the benefit of male teachers for boys. There were no differences in self-efficacy for different school subjects, nor did school subject interact with any of the other variables. The residual variance components (random effects in Table 1) were very similar to those in the variance components model (M1o), indicating that very little of the variance at any level can be explained in terms of the 23 independent variables considered in Model 1 (Table 1).

In Model 2 (M2 in Table 1), a parallel analysis was conducted, with classroom climate perceptions of self-efficacy as the dependent variable. Only 1 of 23 effects was even marginally significant ( $.01 < p < .05$ )—the Science  $\times$  Student Gender  $\times$  Teacher Gender interaction. In contradiction to predictions based on the matching hypothesis, girls rated the self-efficacy class climate higher for science classes taught by men than for those taught by women, whereas boys gave higher ratings for classes taught by women than for those taught by men. Again, the residual variance components were nearly the same as the variance components in M2o, indicating that little variance was explained by the set of 23 predictor variables.

Note. Each dependent variable (the six adaptive motivations) was related to the set of 23 predictor variables (fixed effects; dummy variables representing student gender, teacher gender, year in school, school subject, and all possible interactions) and was included in a set of three models: Model 1 (M1; student self-ratings of their motivation; also see the corresponding variance components model M1o), Model 2 (M2; student self-ratings of classroom climate; also see the corresponding variance components model M2o), and Model 3 (M3; M1 with the addition of class-average ratings of the corresponding classroom climate). All analyses were based on a cross-classified multilevel model with five levels, the random effects: school, teacher, classroom, student, and subject (residual variance term).

\*  $p < .05$ . \*\*  $p < .01$ . \*\*\*  $p < .001$ .

In Model 3, class-average values of classroom perceptions, which were the focus of Model 2, were added to Model 1. There was a large, statistically significant effect of classroom climate on self-efficacy perceptions; self-efficacies were higher in classes in which the classroom climate supported self-efficacy. However, other effects were largely similar to those in Model 1. It is important to note that the residual variance components were somewhat smaller in Model 3 (compared to Model 1 and M1o) because classroom climate had a substantial effect on individual student self-efficacies.

In summary, the self-efficacy results provide no support for predictions based on matching, gender-stereotypic, and gender intensification perspectives (i.e., predictions that boys are better motivated by male teachers). Girls had higher self-efficacies in all subjects, and this gender difference did not vary with subject or age. Although a few Student Gender  $\times$  Teacher Gender interactions were significant, the nature of these interactions was in the opposite direction from that predicted by the matching hypothesis—particularly the predicted benefits of male teachers for boys. Broadly, these results support the gender invariance and similarities model.

*Other adaptive motivations.* The same set of models was applied to the remaining five adaptive motivations (see Table 1). Again, residual variance components in Models 1 and 2 were similar to variance components in M1o and M2o, indicating that the set of 23 predictors did not explain much variance in any of the motivation and classroom climate perceptions.

In Models 1 and 3, girls consistently had higher levels of motivation than boys, but the Teacher Gender  $\times$  Student Gender interactions were nonsignificant for all six adaptive motivations. However, the Year  $\times$  Student Gender  $\times$  Teacher Gender interaction was significant for valuing and marginal ( $.01 < p < .05$ ) for mastery. Girls had similar mastery motivations in classes taught by male and female teachers in both Years 8 and 10, whereas boys had higher mastery motivation in classes taught by female teachers than in classes taught by male teachers in Year 10 but somewhat higher motivation in classes taught by male teachers than in classes taught by female teachers in Year 8. Mastery motivation was higher in science and math than in English but was particularly low in English classes for older students taught by men. However, this effect was similar for boys and girls.

For classroom climate ratings (Model 2), there were few statistically significant effects for any of the other adaptive motivations; only 7 of 115 (23 effects  $\times$  5 motivations) were statistically significant at the nominal .05 level. However, the Student Gender  $\times$  Teacher Gender interaction was significant for two of these scales (value and persistence). For persistence class climate, the effect was marginal ( $.05 < p < .01$ ); ratings of classes taught by women were higher than ratings of classes taught by men for both boys and girls. For male teachers, however, ratings were higher for boys than for girls. For value classroom climate, the Student Gender  $\times$  Teacher Gender interaction varied by subject and year and was only significant for English classes. Whereas climate in English classes taught by female teachers was perceived similarly by boys and girls in both year groups, classes taught by male teachers were rated higher by boys in Year 8 than by boys in Year 10 and lower by girls in Year 10 than by girls in Year 8.

*Maladaptive motivations.* The same set of models was applied to the set of five maladaptive motivations (see Table 2). Variance components for the school and teacher were nonsignificant,

whereas variance associated with the class was significant for four of five classroom climate ratings (all but avoidance) and for two of the motivation scales (handicapping and disengagement). With the possible exception of anxiety, the residual variance components in Model 1 and Model 2 were similar to variance components in M1o and M2o, indicating that the set of predictors did not explain much variance in any of these maladaptive motivation and classroom climate perceptions.

Fixed effects were typically nonsignificant and small for the set of maladaptive scales other than anxiety. For individual student motivation (Models 1 and 3), anxiety was greater in Year 10 than in Year 8. There was a moderate effect of student gender in that girls reported being more anxious than boys, but this student gender difference did not depend on the gender of the teacher. Whereas anxiety was marginally higher in math, this difference was not large. Classroom climates were more anxious in math classes (particularly for girls), science classes, and Year 10. Across all five maladaptive motivations, there were no statistically significant interactions between student gender and teacher gender, and this lack of interaction generalized over school subject and year level.

*Affective outcomes.* The same set of models was applied to the set of five affective outcomes (see Table 3). Unlike earlier analyses, there were statistically significant variance components associated with the teacher for both individual student and climate perceptions of enjoyment and particularly student-teacher relationships, although class-level variance components were also significant. In addition, there were significant class-level effects for two additional individual scales (future and relationship) as well as for all five climate scales.

Given the diverse nature of these affective outcomes, it is not surprising that the pattern of fixed effects did not generalize well across the different outcomes. Important for purposes of the present investigation, there was only one Student Gender  $\times$  Teacher Gender interaction for individual student outcomes (for student-teacher relationships), and the direction of this interaction was not entirely consistent with a matching hypothesis—particularly the benefits of male teachers for boys. Both boys and girls rated their student-teacher relationships as being better in classes taught by female teachers than in classes taught by male teachers. However, the difference in favor of female teachers was much larger for girls than for boys. The nature of this interaction did not vary significantly with school subject and year in school.

Classroom climate perceptions of participation and student-teacher relationships varied in complicated functions of teacher gender, year, and subject. For participation, this was due primarily to the very low climate perceptions in Year 10 English classes taught by men. For student-teacher relationships in Year 10 science, climate perceptions were very high for male teachers, whereas in Year 10 English, perceptions were higher for female teachers than for male teachers. However, none of these effects varied with student gender. More generally, outcomes tended to be more negative in mathematics (enjoyment, future, and resilience) and science (relationship and resilience). While these differences were evident to varying degrees in both individual and class-climate scales, they varied to some extent according to year in school.

In Model 3, there were substantial positive effects of class-average climate scores for each of the individual scales. Indeed, after class-average perceptions of climate were controlled for each

*Note.* Each dependent variable (the five maladaptive motivations) was related to the set of 23 predictor variables (fixed effects; dummy variables representing student gender, teacher gender, year in school, school subject, and all possible interactions) and was included in a set of three models: Model 1 (M1; student self-ratings of their motivation; also see the corresponding variance components model M1o), Model 2 (M2; student self-ratings of classroom climate; also see the corresponding variance components model M2o), and Model 3 (M3; M1 with the addition of class-average ratings of the corresponding classroom climate). All analyses were based on a cross-classified multilevel model with five levels, the random effects: school, teacher, classroom, student, and subject (residual variance term). Unc = uncertain.

\*  $p < .05$ . \*\*  $p < .01$ .

of these affective outcomes, the statistically significant variance components associated with teacher and/or class levels (in Model 1) were no longer significant. There was, however, substantial variation in the sizes of effects for class-average perceptions across the different outcomes, varying from a very large effect of .85 for student-teacher relationships to .69 and .62 for future and enjoyment and .43 and .30 for participate and resilience. In general,

controlling for class-average climate perceptions eliminated the statistically significant variance components associated with teacher and class levels and most of the fixed effects observed in Model 1. Hence, many of the generally small effects on student motivation associated with student gender, teacher gender, school subject, and year in school were mediated by the corresponding measure of classroom climate.

Note. Each dependent variable (the five outcomes) was related to the set of 23 predictor variables (fixed effects; dummy variables representing student gender, teacher gender, year in school, school subject, and all possible interactions) and was included in a set of three models: Model 1 (M1; student self-ratings of their motivation; also see the corresponding variance components model M1o), Model 2 (M2; student self-ratings of classroom climate; also see the corresponding variance components model M2o), and Model 3 (M3; M1 with the addition of class-average ratings of the corresponding classroom climate). All analyses were based on a cross-classified multilevel model with five levels, the random effects: school, teacher, classroom, student, and subject (residual variance term).

Discussion

Gender-Stereotypic Differences, Gender Intensification, and the Matching Hypothesis

Substantively, the overarching focus of the study is whether male teachers are better able to motivate boys, how these effects

vary with year in school and school subject, and the role of classroom climate. We began by reviewing various predictions based on the gender-stereotypic model, the gender intensification model, and the matching hypothesis. It was predicted that boys and girls would be more motivated in gender-stereotypic disciplines (girls in English, boys in math and science) and that these differ-

ences would grow larger with age. According to the matching hypothesis as applied in our study, male teachers should be better able to motivate boys in particular, whereas female teachers should also be better able to motivate girls. However, across a set of cross-classification MLMs applied to six adaptive motivations, five maladaptive motivations, and five affective outcomes, there was little or no support for these predictions. Instead, there was better support overall for the gender invariant and similarities model. There were reasonably consistent gender differences in favor of girls. More important and consistent with Marsh's (1993) invariance hypothesis, the effects of student gender did not vary substantially as a function of school subject, age, or teacher gender.

Consistent with expectations, for all six adaptive motivations, girls were generally more positively motivated than boys. However, contrary to predictions based on the gender-stereotypic model (but consistent with the gender invariance hypothesis), these gender differences in favor of girls generalized across school subjects. Indeed, gender differences favoring girls were as large in math and science as in English (or even larger). Furthermore, these gender differences in favor of girls in different school subjects generalized over age. For the five maladaptive motivations, there were only substantial gender differences in one scale. Girls were considerably more anxious than boys, but these differences did not vary as a function of year in school or school subject. For the remaining maladaptive motivations, there were no significant differences between boys and girls, and this lack of gender difference generalized reasonably well over year in school and school subject. For the set of six outcome variables, girls had more positive outcomes for participation, enjoyment, and student-teacher relationships, but boys had higher resilience scores.

Particularly central to the present investigation were the Student Gender  $\times$  Teacher Gender interactions and predictions that boys would be benefited by having male teachers. There was, however, no support at all for the matching hypothesis for any of the adaptive or maladaptive motivations. Although there were small gender differences (mostly in favor of girls) in some of the motivations, these did not depend on the gender of the teacher. The only statistically significant interaction between student gender and teacher gender for individual student constructs was for student-teacher relationships. For this one outcome, there was partial support for a matching hypothesis. Even here, however, both boys and, particularly, girls felt they had better student-teacher relationships with female teachers than with male teachers. Hence, this does not support the contention that boys are benefited by male teachers; boys were more benefited by female teachers, but less so than were girls.

### *Classroom Climate*

We predicted that there would be statistically significant and substantively meaningful variance components associated with the teacher who taught a class and the particular group of students in a given class. Although these two sources of classroom climate are typically confounded, the design of our study (with multiple classes for each teacher and the same students making ratings of multiple teachers) and the MLM analyses allowed us to disentangle these two sources of variation in class-climate perceptions. The results showed that for both adaptive and maladaptive climate

perceptions there were consistent differences between classes but that these differences did not generalize over different classes taught by the same teacher. This finding has potentially profound implications for classroom climate research, suggesting that the classroom climate in relation to a wide variety of motivational constructs is largely a function of the particular group of students in a class rather than the teacher who teaches the class. We do note, however, that teacher-level variance components (as well as class-level components) were statistically significant for two of the affective outcome variables (enjoyment and student-teacher relationships). Hence, there were some aspects of classroom climate for which the particular teacher made a difference beyond the effects of the particular group of students in the class being taught. We also note that earlier research (Papaioannou et al., 2004) in a physical educational setting showed that classroom motivation climate was more a function of the teacher than of the group of students. Hence, there is a need for further research to test the replicability and generalizability of our results.

Gender differences in classroom-climate perceptions tended to be smaller than the gender differences in the corresponding motivations and outcome variables. Indeed, the only main effect of gender across the 11 motivation and 5 outcome climates was a small effect in favor of boys for planning (even though planning motivation was higher for girls). Even for anxiety and resiliency, for which girls had substantially less favorable scores than boys, there were no gender differences in the corresponding classroom-climate perceptions. Consistent with this finding, variance components associated with students were substantially smaller for class-climate perceptions than for corresponding student motivations. There were, however, a number of statistically significant effects of school subject and year in school on classroom-climate perceptions, which sometimes interacted with student gender. Girls perceived the management climate to be stronger in math and science classes than did boys. Anxiety classroom-climate perceptions were higher in mathematics and science than English and higher in Year 10 than Year 8, but girls perceived the anxiety and disengagement climates to be larger (more maladaptive) in math classes than did boys. In general, however, there was good agreement between boys and girls in terms of their perceptions of classroom climates.

### *Significance and Implications of Findings*

Counter to popular arguments that boys fare better academically under male teachers, there was little or no support for the matching hypothesis for either motivation or the outcome variables considered here. Taken as a whole, this argument supports previous contentions by MLM research (Hill & Rowe, 1996; MacDonald, Saunders, & Benfield, 1999; Rowe, 2000; Rowe & Rowe, 2002) that where there is a class or teacher impact on academic outcomes, it is probably the nature of pedagogy that is critical and not the gender of the person delivering it. This is also consistent with previous qualitative work (Martin, 2002, 2003a; Martino & Meyenn, 2002) that has shown that it is the nature of pedagogy, rather than demographic-type variables, that students are most concerned about.

Gender differences were not large and, where significant, tended to favor girls. Anxiety and persistence, however, were exceptions to this generalization in that boys had more favorable scores on

these scales than girls. Although they are consistent with previous research (Martin, 2001, 2002, 2003a, 2003b, 2003c, 2003d, 2004, 2007; Martin & Marsh, 2005), our results based on a cross-classified MLM extend previous research. The education of boys has been an issue of ongoing debate, research, and policy implementation over the past decade (Weaver-Hightower, 2003). It appears that boys' and girls' educational outcomes are most divergent during the period of adolescence, with a large body of data attesting to the differences between adolescent boys and girls in academic motivation and achievement and the comparative maturity and conscientiousness of girls' approach to their studies during this time (e.g., Collins, Kenway, & McLeod, 2000; Lingard, Martino, Mills, & Bahr, 2002; Martin, 2004). In reviews attempting to identify strategies to enhance boys' flagging motivation, literacy, and achievement (Lingard et al., 2002; Martin, 2004), there is consistent reference to the importance of supportive and affirming relationships in promoting the educational outcomes of boys. Given this, it is interesting to note that in relation to the present data, it was on the teacher-student relationship measure that most variance existed at the teacher and class levels. Another key finding is that the bulk of variance in motivation occurred at the student level, indicating that the motivation level of an individual student generalized reasonably well over different classes and different school subjects. In contrast, as expected, student perceptions of classroom climate were much more specific to a particular class taught by a particular teacher. Whereas there was weak evidence in support of class and teacher effects for individual student motivation, these effects were stronger for classroom-climate perceptions. However, even for motivational climate perceptions where class-level effects were significant, there was little evidence that the effects of a particular teacher in one class generalized to other classes taught by the same teacher. It was only with two affective outcomes (enjoyment and student-teacher relationships) that there were significant teacher effects—in addition to class effects. Findings, then, hold implications for educational intervention, suggesting that researchers should focus on individual students in addition to the teacher and the class composition.

Notwithstanding the substantial variance at the student level on individual measures, it is clear that teachers had a significant effect at the climate level—specifically enjoyment and student-teacher relationship. Indeed, a variety of studies reflect this. Students who believe their teacher is a caring one also tend to believe they learn more (Teven & McCroskey, 1997). Students' feelings of acceptance by teachers are associated with emotional, cognitive, and behavioral engagement in class (Connell & Wellborn, 1991). Specific strategies teachers can use to develop motivation and engagement in the classroom were detailed in Martin (2001, 2005, 2006b, in press; see also Martin & Marsh, 2005). Also raised by Martin (2006b) in previous teacher-related motivation and engagement research was the role of professional development in enhancing students' motivation and engagement.

Findings also suggest that the composition of the class is relevant to students' motivation and engagement. Indeed, given that in recent years there has been substantial focus on teacher effectiveness and the development of taxonomies and criteria of effective teaching, it might now be important to revisit the class composition. In particular, there is now a need for research focusing on the characteristics of effective classrooms (including but not restricted to characteristics of effective teaching), the students collected

together in the classroom, and the bases on which they are collected together. Obviously, prior work has been conducted into cognate issues, such as seating arrangement (Hastings & Schwieso, 1995; Marx, Fuhrer, & Hartig, 1999), streaming (Marsh, 1987a; Marsh & Hau, 2003), and single-sex class composition (Martin, 2004; Martin & Marsh, 2005); however, class composition as it is relevant to motivation and engagement is an avenue for further research, and multilevel techniques are well placed to provide valuable input.

### *Limitations and Future Directions*

The present study provides much information on the role of student-, class-, and school-level variance in explaining motivation in mathematics, English, and science and also sheds further light on the role of student gender and teacher gender in contributing to students' motivation and perceptions of classroom climate. There are, however, a number of potential limitations that are important to consider when interpreting of findings that also provide direction for further research.

The data presented in this study were all self-reported, some based on self-report responses by individual students and others based on the class-average responses drawn from groups of students. Although this is a logical and defensible methodology in its own right, given the substantive focus, it is important to conduct research that examines the same constructs using data derived from additional sources—for example, from teachers and parents—and also using different methodologies and paradigms, such as structured interviews or observation (see Dowson & McInerney, 2003; Martin, Marsh, Williamson, & Debus, 2003) as well as other multimethod approaches to the issue (Marsh, Martin, & Hau, 2006). Inclusion of achievement data is also relevant.

It is important to recognize that our study was based on only five schools; this limits generalizability to other schools and is also weak in terms of testing variance components at the school level. Future research needs to be conducted that includes a larger number and a wider variety of schools. Furthermore, although we had a large number of teachers in the study, we did not have a large number of classes taught by the same teacher. For this reason, our conclusion that motivation and classroom climate are more a function of the class of students than the teacher should be interpreted cautiously. Indeed, because there were only small effects of either teacher or class—particularly in relation to motivation—it might be a moot issue as to how much of this effect is associated with the teacher rather than the particular group of students within a given class. Nevertheless, the approach used here is a potentially important contribution to further research into this issue—in relation to class climate, which was our focus, but also in relation to other outcomes, such as achievement test scores. Hence, it would be useful in future research to collect data for a larger number of different classes taught by the same teacher to provide a stronger test of our conclusion that classroom climate is as much as or more a function of the group of students rather than the teacher.

Further on this issue of data collection, it is important to recognize that the data were collected at one time point, so future longitudinal work is needed to explore the stability of constructs over time and to provide greater scope to partial out residual variance, which in this study was manifested in student-level variance. Employment of longitudinal research also has the poten-

tial to clarify and uncover the possible motivational fluctuations across time (Bong, 1996; Jacobs, Lanza, Osgood, Eccles, & Wigfield, 2002). It would be particularly useful to evaluate changes in motivational and classroom climate perceptions at critical educational-stage transitions (e.g., from junior high school to middle high school to senior high school), although the timing and importance of such transitions will vary with the particular school system.

A major finding in the present study was that there was little or no evidence to support the benefit of male teachers for boys. This finding runs counter to the gender-stereotypic model and some popular claims and beliefs that boys' academic development is dependent on there being ample presence of male teachers in their academic life. In relation to this, it is important to consider carefully the generalizability of this finding. First, it does not necessarily apply to younger children, because the data collected in this study were from middle and high school students only. Similar research is needed at the elementary school level to ascertain the generalizability of the finding to younger children. Second, the finding does not necessarily apply to other emotional and psychosocial dimensions of students' lives not considered here. It may well be, for example, that boys prefer male teachers when dealing with emotional and personal issues, just as girls may prefer female teachers (Martin, 2002, 2003a). Indeed, this might suggest that the debate about the need for male teachers in boys' lives (and female teachers in girls' lives) confuses teachers with role models. This points to the need for research that seeks to understand in greater detail the congruence (or lack thereof) between teachers and role models, how the two differ, how they are similar, the extent to which one can be the other, and the gender-relevant issues involved.

Our findings suggest that climate effects associated with a class are due to the particular group of students and their characteristics, as much as or more than the effects associated with the teachers who teach the class, which generalize over different classes taught by the same teacher. Although the findings are substantively important, with significant implications for class-climate research, it is important not to overgeneralize interpretations of these results. Because the innovative design and methodological approach used here are not common in classroom-climate research (or teacher effectiveness research more generally), it is important to test the generalizability of these findings with other constructs where teacher effects might generalize better over different classes (e.g., teacher effectiveness, achievement, and other outcomes). Indeed, our research showed that there were generalizable teacher effects for two of our outcome variables (enjoyment of the class and student-teacher relationships). Furthermore, research on students' evaluations of teacher effectiveness (Marsh, 1987b, 2007b) shows that ratings of overall teacher effectiveness and even the profile of responses to specific components (e.g., learning, enthusiasm, organization, rapport, workload difficulty) generalize very well over different classes taught by the same teacher. This suggests that teacher effects are likely to be larger and more generalizable for constructs more closely aligned to actual teacher behaviors than for constructs more closely aligned to individual student characteristics, such as those considered here.

## Conclusion

The present study used cross-classified MLMs to determine the contribution of student gender and teacher gender across junior and middle high school classes in math, English, and science and the relative salience of student, class, and school variance in boys' and girls' academic motivation and corresponding classroom climates. As expected, of the few significant main effects that emerged, most of them were in girls' favor. Motivation did not vary substantially for boys and girls as a function of the teacher's gender, thus supporting the gender invariant and similarities model and calling into question the gender-stereotypic model and matching hypothesis for student motivation. Findings also demonstrated that the bulk of variance in motivation occurred at the student level. Individual student measures of motivation yielded few statistically significant class-level variance components, and no teacher-level components were significant. Taken together, the findings of the present investigation hold substantive and methodological implications for researchers studying issues relevant to motivation and classroom climate and are also relevant to educators seeking to enhance educational outcomes that rely in large part on the extent to which their students are affectively, cognitively, and behaviorally engaged.

# A Multilevel Study of Predictors of Student Perceptions of School Climate: The Effect of Classroom-Level Factors

Christine W. Koth, Catherine P. Bradshaw, and Philip J. Leaf

Johns Hopkins Bloomberg School of Public Health and the Johns Hopkins Center for the Prevention of Youth Violence

A positive school climate is an important component of successful and effective schools and thus is often an aim of schoolwide initiatives. Climate has traditionally been conceptualized as a school-level factor and is often assumed to be related to other school-level factors (e.g., school size). The current study examines variation in perceptions of climate based on individual-, classroom-, and school-level factors to determine the influence of predictors at multiple levels. Data come from 2,468 5th graders from 37 public elementary schools. Two aspects of students' perception of school climate, order and discipline, and achievement motivation are examined. Multilevel analyses in hierarchical linear modeling indicate that individual-level factors (race and sex) accounted for the largest proportion of variance in perceptions of school climate. School-level factors (e.g., school size and faculty turnover) and several classroom-level factors (e.g., characteristics of the teacher, class size, and the concentration of students with behavior problems) were also significant predictors of perceptions of climate. These findings suggest that characteristics of the classroom environment are important to consider when aiming to improve school climate.

*Keywords:* school climate, multilevel analysis, classroom environment, behavioral problems

Positive school climate is recognized as an important component of successful and effective schools (Brand, Felner, Shim, Seitsinger, & Dumas, 2003; Kreft, 1993; Miller & Fredericks, 1990). It is defined as shared beliefs, values, and attitudes that shape interactions between students, teachers, and administrators and set the parameters of acceptable behavior and norms for the school (Emmons, Comer, & Haynes, 1996; Kuperminc, Leadbeater, Emmons, & Blatt, 1997). School climate is a product of social interactions among students and with teachers, is influenced by educational and social values, and has been shown to relate to social situations within classrooms and to the school as a whole. It has been linked to academic achievement and performance (Battistich, Solomon, Kim, Watson, & Schaps, 1995; Griffith, 1999); student misconduct, aggression, and behavioral problems (Battistich & Hom, 1997; Battistich, Solomon, Kim, Watson, & Schaps, 1995; Kuperminc, Leadbeater, & Blatt, 2001; Kuperminc et al., 1997; Loukas & Robinson, 2004; Shochet, Dadds, Ham, & Montague, 2006; Welsh, 2000; Wilson, 2004); adjustment problems (Kuperminc et al., 1997); and social and personal attitudes (Battistich et al., 1995).

This multidimensional construct has been examined from different theoretical and methodological perspectives. Prior research

has typically assessed teachers and school staff to investigate their perceptions of school organization and identify specific attributes that distinguish effective from ineffective schools (Stockard & Mayberry, 1992). Recently, there has been increased interest in students' perceptions of the school environment among educators, researchers, and policymakers (Brand et al., 2003; Griffith, 1995, 1999, 2000; Kuperminc et al., 2001, 1997; Van Horn, 2003; Verkuyten & Thijs, 2002; Vieno, Perkins, Smith, & Santinello, 2005; Welsh, 2000).

From a social cognitive perspective (Bandura, 2001; Rogers, 1951), people tend to react to experiences as they subjectively perceive them, not necessarily to how the experiences are objectively. Consequently, students' perceptions of the school environment likely have a significant impact on their behavior at school and thus are important potential targets for school improvement initiatives that aim to enhance achievement and reduce discipline problems (Haynes, Emmons, & Ben-Avie, 1997). Since the No Child Left Behind Act of 2001, two aspects of school climate—achievement and safety—have become central in schools' improvements. A wide range of interventions have been proposed to address climate, some of which are aimed at individuals and others of which are more focused on classrooms or the school level. However, the impact of interventions on achievement and safety may depend on the target of the intervention. Therefore, it is important to identify specific factors at different ecological levels (student, classroom, and school) that may influence students' perceptions of these two aspects of school climate.

## Measuring School Climate

School climate is multidimensional in nature, and an important issue is determining the appropriate unit of analysis: individual students or groups of students. Most previous research has con-

ceptualized climate as a property of the school and analyzed it at the school level (see Anderson, 1982, for a review). Typically, an indicator of the climate is assessed and correlated with indicators of students' average performance, school characteristics, or student body composition (e.g., Brookover, Schweitzer, Schneider, Beady, Flood, & Weisenbaker, 1978; Halpin & Croft, 1963; Walberg, 1968; Walberg & Anderson, 1968). However, aggregating individual ratings data to form a single group-level indicator assumes little variation in the perception of different groups within the school (i.e., students, teachers, and administrators) and precludes investigation of diversity in perceptions of the climate.

Not all researchers view climate as an organizational indicator. Several studies have emerged documenting significant variation both within schools (likely attributable to individual-level factors) and between schools (likely attributable to school-level factors), thereby illustrating the importance of a multilevel approach (Battistich et al., 1995; Bevans, Bradshaw, Miech, & Leaf, 2007; Brand et al., 2003; Griffith, 1999, 2000; Philips, 1997; Rowan, Raudenbush, & Kang, 1991; Van Horn, 2003; Vieno et al., 2005). Specifically, student-level factors such as race (Battistich et al., 1995; Griffith, 2000; Kuperminc et al., 2001, 1997) and sex (Battistich et al., 1995; Griffith, 1999, 2000; Kuperminc et al., 2001, 1997; Verkuyten & Thijs, 2002; Welsh, 2000) have been shown to be significantly related to perceptions of school climate, with male and minority students tending to perceive the environment less favorably.

Commonly examined school-level predictors of school climate include structural aspects of the school, such as school size (Griffith, 2000; McNeely, Nonnemaker, & Blum, 2002; Welsh, 2000), student-teacher ratio (Griffith, 1995), and student mobility (Griffith, 2000). Aggregated indicators of student characteristics (e.g., socioeconomic status and ethnicity; Battistich et al., 1995; McNeely et al.; Vieno et al., 2005) and school type (public vs. private or urban vs. rural; Vieno et al., 2005) have also been linked with perceptions of school climate. However, relatively few studies have investigated factors at the classroom level in relation to perceptions of the overall school climate.

### Classroom-Level Predictors of School Climate

Classroom dynamics are complex and similar to school climate in that they involve the relationships and interactions between teachers and students, among students, and the perceptions, attitudes, and behaviors of students and teachers within the classroom (Montague & Rinaldi, 2001). It is likely that the climate of specific classrooms varies within a single school and that classroom management, class composition, and teacher characteristics may influence students' experiences. Research has suggested that teacher management style is related to the social structure of the class (Roland & Galloway, 2002). Teachers with practices that include emphasis on prosocial values and cooperation and teachers who were supportive have experienced improvements in positive student behavior and an increase in students' perception of connectedness (Solomon, Battistich, Kim, & Watson, 1996). Classroom variables that are more descriptive such as gender and ethnic composition and class size have also been investigated. Two studies of Dutch students incorporated these descriptive variables into their analyses but found no significant effects in relation to school satisfaction (Verkuyten & Thijs, 2002) and school adjust-

ment (van der Oord & Van Rossem, 2002). Similarly, teacher characteristics such as full- versus part-time status and work experience have also been investigated (van der Oord & Van Rossem, 2002) and linked with students' perceptions of climate.

Another potential classroom-level predictor of perceptions of school climate is the students' proximal exposure to deviant or aggressive behavior in the classroom. A study of 134 first-grade classrooms found considerable variability in the level of aggressive behavior across classrooms within schools and that the children's social behaviors varied as a function of the group norm (Stormshak et al., 1999). Furthermore, a growing number of studies have shown that groups of children with a high concentration of aggressive members affect both the behavior of the members and the dynamics of the group itself. In a study of first-grade classroom environments, classes with a higher proportion of students with past behavior problems also had significantly higher teacher ratings of shy behavior (Werthamer-Larsson, Kellern, & Wheeler, 1991). Research has also demonstrated that aggressive or deviant children shift the social norms, such that deviant behavior becomes socially acceptable among the members (Wright, Giammarino, & Parad, 1986). In addition to increasing the risk for behavior problems among classmates (Dishion, McCord, & Poulin, 1999; Dishion, Spracklen, Andrews, & Patterson, 1996; Patterson, Dishion, & Yoerger, 2000; Thornberry & Krohn, 1997), aggregating or clustering deviant youths within classrooms may have a proximal (Bronfenbrenner & Ceci, 1994) negative influence on the classroom environment and affect the students' overall perception of the school climate. Taken together, these findings suggest that the concentration of children with behavior problems may be an important classroom-level factor to consider when examining variation in children's perception of the school environment.

Although the notion that classroom characteristics influence students' overall perception of school climate seems reasonable, few studies have actually examined the various individual and classroom characteristics simultaneously (Malin & Linnakylae, 2001). The vast majority of multilevel research on school climate has used two-level models. For example, Verkuyten and Thijs (2002) found that factors at both the individual level (sex and minority status) and the class level (average motivation for academics and incidence of peer victimization) were related to students' overall perceptions of the school climate. Research using three-level multilevel modeling (individual, class, and school) is even rarer (e.g., Vieno et al., 2005). In a study of Italian school children, Vieno et al. (2005) found that 84% of the effect on climate was accounted for by individual-level factors (e.g., student's sex, age, socioeconomic status, parental monitoring, and control), whereas 11% was accounted for by class-level factors (e.g., democratic classroom culture) and 4% by school-level factors (e.g., school size, private vs. public, extent of extracurricular activities, and school resources). These findings suggest that attempts to identify the causes and consequences of school climate could benefit from examining potential predictors at multiple levels of the child's ecology (Griffith, 1999, 2000).

### Overview of the Current Study

The present study examined two distinct aspects of school climate (school safety and willingness to learn) to determine the

potential influence and relative contribution of factors at various levels (individual, classroom, and school). We investigated previously established associations between school climate and individual-level (e.g., race and sex) and school-level factors (e.g., school enrollment and students' average income level) as well as classroom-level factors. Specifically, we predicted that classroom indicators (e.g., class size and concentration of students with behavior problems) and teacher characteristics (e.g., advanced education and number of years teaching at the school) would have a proximal influence on students' perceptions of the school climate, above and beyond the influence of individual- and school-level factors. Using a multilevel framework, we were able to isolate the amount of variance associated with factors at the individual, classroom, and school levels.

## Method

Data for this study were collected as part of a large-scale study of a schoolwide behavior support program called Positive Behavioral Interventions and Supports. Thirty-seven Maryland public elementary schools from five school districts (rural and suburban) volunteered to participate in the study. Of the schools, 21 were randomized to the intervention condition and 16 were assigned to the comparison condition. The current study includes data from the first year of the trial only, and no significant intervention effects were observed on student reports of the school climate at this time point.

## Participants

The sample included 2,468 students in 120 non-special education fifth-grade classrooms within 37 elementary schools. The student sample was 48.8% female, and the racial and ethnic breakdown of students was 45.1% Caucasian, 34.5% African American, 3.2% American Indian, 2.2% Asian, and 15% "other" or "multiethnic." Of the 120 fifth-grade teachers included in the current analyses, 81.7% were female, 85.0% were Caucasian, 61.3% had been teaching at the school for 4 or fewer years, and 55.8% had education equivalent to or above a master's degree. The fifth-grade class sizes ranged from 11 to 31 students ( $M = 23.1$ ,  $SD = 3.7$ ). Total school enrollment ranged from 239 to 881 students ( $M = 488.4$ ,  $SD = 146.7$ ). The percentage of school-level (teaching) faculty turnover ranged from 0% to 40.0% ( $M = 13.1$ ,  $SD = 8.9$ ), and student mobility ranged from 5.7% to 47.9% ( $M = 24.5$ ,  $SD = 10.2$ ). The percentage of students receiving free or reduced-price meals ranged from 7.3% to 80.5% ( $M = 40.8$ ,  $SD = 20.0$ ).

## Measures

*Student (Level 1).* In the spring, all fifth-grade students at participating schools were asked to complete the elementary school version of the School Development Program School Climate Survey (Haynes, Emmons, & Ben-Avie, 2001). The School Climate Survey is a widely used (e.g., Kuperminc et al., 2001) and well-validated measure of students' perception of climate. Prior research by Haynes et al. (2001) has indicated that the measure has strong psychometric properties, including internal consistency and interrater reliability. The School Climate Survey assesses student

demographic information (e.g., sex and race) and consists of 53 statements regarding current school conditions, which are coded as "agree" or "disagree." Two subscales, Order and Discipline and Academic Motivation, were analyzed in the current study. Because of the study design, only fifth-grade students were asked to complete the School Climate Survey subscales; no data were collected from students in other grades. The survey subscales were group administered by trained project staff members, who provided a brief overview of the purpose of the survey and read each question aloud as the students completed the survey. The individual surveys were anonymous but were linked to the student's homeroom teacher.

The Order and Discipline subscale consists of 11 items (e.g., "My school is a safe place," "Children in my school fight a lot," and "At my school children disobey the rules") and assesses school safety and the appropriateness of student behavior at school. The Achievement Motivation subscale consists of six items (e.g., "My teachers believe I can do well in my school," "I feel I can do well in this school," and "I enjoy learning at this school") and assesses the extent to which the students believe they can and are willing to learn. Negatively stated items were reverse scored such that a higher score indicates a more positive school climate. The subscale scores were calculated by computing the percentage of items students agreed with on a scale ranging from 0 to 100. Analyses of the internal reliabilities of these two subscales indicated that the Order and Discipline subscale had a Cronbach's alpha of .74, and the Achievement Motivation subscale had an alpha of .63. Preliminary analysis using ordinary least squares (OLS) regression on individual student school climate scores and clustering on school (with robust standard errors) revealed no significant differences between intervention and comparison schools on either the Order and Discipline subscale ( $p = .39$ ) or the Achievement Motivation subscale ( $p = .85$ ).

*Teacher and classroom (Level 2).* Teachers completed a brief demographic questionnaire in the fall including questions regarding their gender, education, and number of years teaching at this school (with 4 years or less indicating newer teachers and 5 years or more indicating established teachers). Teacher ratings of individual students' disruptive or aggressive behaviors were obtained in the spring using the Teacher Observation of Classroom Adaptation—Checklist (Leaf, Schultz, Keys, & Ialongo, 2002). This checklist contains 25 items on a 6-point scale ranging from 1 (*never*) to 6 (*almost always*). The Aggressive/Disruptive subscale was used to calculate the percentage of students exhibiting behavior problems within each classroom and includes nine items (e.g., "breaks rules," "fights," "harms property," and "teases classmates"). The subscale scores were calculated by first averaging the nine items (Cronbach's  $\alpha = .93$ ) and then applying a cutoff to categorize students as displaying either adaptive behavior or problematic behavior. The cutoff was approximately 1 standard deviation above the total sample mean, such that 25.7% of the students across the full sample of participants were classified as exhibiting problematic behavior. Similar methods have been used to classify students in previous studies using versions of the Teacher Observation of Classroom Adaptation—Revised (August, Bloomquist, Lee, Realmuto, & Hektner, 2006; Petras, Chilcoat, Leaf, Ialongo, & Kellam, 2004; Schaeffer, Petras, Ialongo, Poduska, & Kellam, 2003; Lavalley, Bierman, & Nix, 2005; Stormshak et al., 1999). We then created a single concentration of students with behavior

problems score for each classroom by dividing the number of students classified with problematic behaviors in each class by the total number of students in the class. This procedure resulted in a mean of 26.0% ( $SD = 19.7$ ) of students per class being designated as exhibiting disruptive behavior.

*School characteristics (Level 3).* School enrollment, faculty turnover (percentage of faculty new to the school that year), student mobility (number of students migrating in plus the number migrating out, divided by total enrollment), and average student household income (percentage of students receiving free or reduced-price meals) were obtained from the Maryland State Department of Education for the school year. The receipt of free or subsidized lunches has been shown to be a good marker for low household income (Ensminger et al., 2000).

## Analyses

Preliminary descriptive analyses were conducted in STATA 9.2 (StataCorp, 2005) and indicated that the means for the Order and Discipline and Achievement Motivation subscales were 48.86 ( $SD = 22.94$ ) and 60.10 ( $SD = 27.24$ ), respectively. In addition, the two climate outcomes were correlated at .42. We used a multilevel approach to examine our main hypothesis that the clustering of students within classrooms accounts for a substantial portion of the variance in perceptions of school climate, above and beyond variation between students and the amount of variance accounted for clustering students within schools. Furthermore, we hypothesized that specific classroom-level factors, such as teacher characteristics and indicators of classroom disorder (e.g., large class size, high concentration of students with behavior problems) would be associated with student perceptions of school climate, even after controlling for individual- and school-level factors. We also explored possible within-level interactions separately for each level. A multilevel modeling technique was selected for the present study because both the data (students nested within classrooms nested within schools) and the hypotheses (the impact of school- and classroom-level factors on students' perceptions) are multi-level in nature (Raudenbush & Bryk, 2002). Single-level models are inappropriate for the current analyses because they assume that regression coefficients apply equally to all contexts (Duncan, Jones, & Moon, 1998; Luke, 2004). In addition, because individuals from the same school contexts will likely have correlated errors, a basic assumption of multivariate regression is violated (Luke, 2004). Multilevel modeling procedures account for non-independence of observations (students within classrooms, within schools) and allow for correlated error structures.

To examine the impact of students' perceptions within classrooms clustered within schools, we estimated three-level hierarchical linear models using HLM 6.02 software (Raudenbush, Bryk, & Congdon, 2005). All outcomes of school climate were measured at the student level (Level 1). Additional Level 1 indicators included individual student characteristics, Level 2 indicators included teacher and classroom variables, and Level 3 indicators included school characteristics. For each school climate outcome, an unconditional model with no covariates was estimated to partition the variance across the three levels. Two additional multilevel models were estimated for each outcome. First, Level 1 and Level 3 covariates were introduced to the model, then, to examine the influence of classroom-level factors above and beyond the

influence of other-level factors, the Level 2 covariates were added to the model with the Level 1 and Level 3 covariates. At each step of the model building, each parameter was inspected individually to assess the significance of the residual variance. Any covariates with nonsignificant variances were fixed (Hox, 1995; Raudenbush & Bryk, 2002). Model assumptions were carefully checked for each outcome. The assumption of homogeneity of residuals was tested by examining the normal probability plot of residual dispersion and the scatter plot of the Level 2 expected versus fitted scores (Luke, 2004; Raudenbush & Bryk, 2002). There was no evidence to suggest heteroscedasticity of the residuals. In addition, the possibility that the predicted values fell outside of the 0–100 range was examined. The data revealed that all values fell within that range. Maximum likelihood estimation with robust standard errors was used to estimate the parameters, and the overall fit of the models was evaluated on the basis of examination of the Akaike information criterion (Akaike, 1974) and the likelihood ratio test (Luke, 2004; Raudenbush & Bryk, 2002).

## Results

### Unconditional Model

Using HLM, we calculated the amount of variance for each of the three levels (student, classroom, and school) by fitting an unconditional model (without any covariates) for each school climate outcome (Raudenbush & Bryk, 2002). The partitioning of variance for each outcome is displayed in Table 1. The majority of the variance (65% for order and discipline and 86% for achievement motivation) was explained by between-student variation, and the clustering of students within schools accounted for an additional 5% to 27% of the variance in perceptions of achievement motivation and order and discipline, respectively. Whereas the majority of previous studies did not examine the clustering of students within classrooms, these analyses indicated that clustering at this level accounted for an additional 8%–9% of the total variance in student perceptions of order and discipline and achievement motivation, respectively. These findings illustrate the potential importance of considering variation on a classroom level.

### Multivariate Results

*Within-level interactions.* Using STATA, we conducted a series of single-level OLS regression analyses for each of the three levels of the hypothesized models to explore the possibility of within-level interactions to be included in the subsequent HLM multilevel models. Each OLS regression was clustered on schools

Table 1  
*Partitioning of Variance Across Levels From the Unconditional Multilevel Models for Students' Perceptions of Order and Discipline and Achievement Motivation*

Level	Order and discipline variance (%)	Achievement motivation variance (%)
1: Student	65	86
2: Classroom	8	9
3: School	27	5

to better estimate the standard errors. No significant interactions were found between the covariates within the Level 1 (student) or Level 3 (school) variables. Using the Level 2 data, an interaction between class size and number of years a teacher has been teaching at the school (newer teachers = 4 years or less and established teachers = 5 years or more) was detected. For ease of interpretation, the class size variable was centered at the grand mean ( $M = 23.1$ ). A single-level OLS regression indicated that this interaction was statistically significant for order and discipline ( $p = .04$ ) and achievement motivation ( $p = .03$ ). The calculated interaction term was entered as a separate Level 2 variable in the multilevel models to examine the association of the interaction within the multilevel framework.

**HLM.** Multilevel model estimates for order and discipline and achievement motivation are displayed separately in Table 2. Model

1 contains student-level (Level 1) and school-level (Level 3) covariates, and Model 2 contains estimates when the classroom (Level 2) covariates are added together with student- and school-level covariates. In Model 1, students' race and sex were significant for both of the school climate subscales. These associations remained in Model 2 when classroom-level covariates were added. These findings indicate that male and minority students perceived the school climate less favorably than did female and Caucasian students. Regarding the school-level factors in Model 1, the percentage of students from lower income households was statistically significant for order and discipline; however, when classroom factors were added to the model, this relation did not remain statistically significant.

We then included the classroom-level factors in the models to determine whether the individual- and school-level influences re-

mained significant (see Model 2 in Table 2). There were no significant changes in individual-level factors when compared with Model 1. Regarding the school-level factors, faculty turnover was related to order and discipline, such that students from schools with higher turnover described the school as less orderly. With regard to school enrollment, we found that larger schools tended to be associated with lower scores on achievement motivation in Model 1, and this association became statistically significant in Model 2 when accounting for classroom-level factors.

Focusing on the classroom-level factors (see Model 2 of Table 2), we found the percentage of disruptive students in a class to be negatively associated with both indicators of school climate. Students in classrooms with a greater number of disruptive students rated the school climate less favorably than did students in classrooms with fewer disruptive peers. The within-Level 2 interaction (class size and number of years teaching at the school) remained significant for order and discipline and achievement motivation in the multilevel analyses. This interaction term represents the difference in school climate as class size increases among students of more established teachers compared with students of newer teachers. For both order and discipline and achievement motivation, the interaction coefficient was negative, indicating that in larger size classes, the students of more established teachers perceived the school climate less favorably than did students of newer teachers. The coefficient for class size was positive and statistically significant for achievement motivation and represents the change in school climate scores of students of newer teachers in larger versus smaller classes; therefore, for students with newer teachers, a larger class size was associated with a more positive academic setting than was a smaller class size. Because class size was mean-centered, the coefficient for years teaching represents the difference in school climate scores between established and newer teachers with an average class size of 23 students and was statistically significant for order and discipline. In other words, students of more established teachers in average-sized classrooms reported a more orderly climate than students of newer teachers in average-sized classrooms.

**Model fit.** A series of fit indices were calculated to evaluate the fit of the data to the final models. As shown in Table 2 for the two school climate variables, the models with student-, classroom-, and school-level covariates had lower Akaike information criteria (indicating better fit) and a significant difference in the likelihood ratio test ( $p < .01$ ) as compared with the models with only student- and school-level covariates.

## Discussion

The present study used a multilevel framework to examine the influence of individual-, classroom-, and school-level factors on students' perceptions of school climate. When we unpack these influences across levels in the unconditional model, we see that the largest proportion of variance comes from individual-level factors (65%–86%; Table 1). Further inspection of proportion of variance across the three levels for each of the climate outcomes indicates that achievement motivation had the lowest amount of school-level variance (5%) and the highest amount of individual-level variance (86%). The proportion of variance suggests there is greater variability in students' willingness to learn within schools and that this aspect of school climate may be more indicative of individuals'

own motivation than is overall aggregated perception. In contrast, the amount of school-level variance for order and discipline was much higher (27%), suggesting that perceptions of school safety may be more relevant to school characteristics than achievement motivation; however, the individual level still accounted for the majority of the variance. Last, 8% to 9% of the variance across the two climate outcomes was attributable to clustering at the classroom level. This partitioning of variance is relatively consistent with previous research by Vieno et al. (2005), who found that 84% of the variation in climate was accounted for at the individual level, whereas 11% was accounted for at the class level, and just 4% at the school level.

From a methodological perspective, these findings suggest that researchers should pay careful attention to the clustering of students, both within schools and within classes, when examining school climate in intervention trials or cross-sectional epidemiological studies (Luke, 2004). Overlooking the nesting of students would likely increase the Type I error rate; therefore, researchers should adjust the standard errors to obtain accurate estimates (Murray, 1998).

## Individual-Level Factors

Consistent with previous research (Battistich et al., 1995; Griffith, 1999, 2000; Kuperminc et al., 2001, 1997; Verkuyten & Thijs, 2002; Welsh, 2000), individual-level factors such as race and sex were associated with perceptions of the school environment, with male and minority students tending to perceive the school less favorably. Male students reported less order and discipline and lower levels of achievement motivation even after controlling for school- and classroom-level factors in Model 2. Prior research has indicated that boys are more likely than girls to display disruptive behavior at school (Lahey et al., 2000; McDermott, 1996; Putallaz & Bierman, 2004; Roberts & Baird, 1972; Tremblay et al., 1996) and therefore may perceive the environment as less safe and orderly. With regard to achievement motivation, boys tend to receive lower grades in elementary school than girls, which may contribute to this difference in their willingness to learn. With regard to race, minority students perceived the environment as less safe and reported lower levels of achievement motivation than did Caucasian youths, even after controlling for classroom- and school-level factors. These findings may reflect cultural differences in the expectations in the school setting (Zimmerman, Khoury, Vega, Gil, & Warheit, 1995) or in the construct validity of school climate (Kuperminc et al., 1997). Interventions that aim to increase a sense of positive climate should raise mutual understanding and awareness of culturally linked expectations in schools.

## School-Level Factors

A series of school-level factors, including school size, faculty turnover, student mobility, and student free or reduced-price meals rate, were also examined as predictors of student perceptions of the school environment. These effects were smaller than we had anticipated. Specifically, larger enrollment was significantly negatively associated with achievement motivation, and high faculty turnover was related to lower perceptions of order and discipline, after controlling for influences at the other two levels. Although

prior research suggests that elementary school students can begin to feel lost or disconnected in large schools (Hellman & Beaton, 1986), Griffith (2000) did not find school size to be a significant factor in students' perceptions of school climate. These discrepant findings suggest that school size may be related to some aspects of school climate but not to others, and additional research with a larger sample of more diverse schools may further clarify the potential association between variables typically considered to be school-level indicators of school disorder (Birnbaum et al., 2003) and students' perceptions of school climate.

### *Classroom-Level Factors*

As hypothesized, some of the classroom-level variables were associated with students' perceptions of the school environment. Of particular interest is the impact of clusters of students with behavior problems. As expected, the greater the proportion of students with behavior problems in a classroom, the less favorably the students perceived the school environment. This effect was strongest for perceptions of order and discipline. These findings suggest that children are particularly sensitive to their classmates' behavior problems and that students perceive the school's safety and their willingness to learn in relation to the number of disruptive classmates.

We detected a significant interaction effect between class size and number of years teaching for both outcomes. Regarding order and discipline, in an average class size of 23, students with more established teachers perceived school climate as safer than did students with newer teachers. Given just this information, one might theorize that teachers who have been working at the school for several years are better integrated into the school, able to provide a more stable and predictable environment for the students, and more familiar with the students. However, the significant interaction term indicates this is not true for all students and teachers. Specifically, students in larger classes with more established teachers tended to view the school environment as less safe than did students in smaller classes with more established teachers. In addition, students in larger classes with newer teachers perceived the school environment as safer than those in smaller classes with newer teachers. Regarding achievement motivation, there was no statistical difference in students' willingness to learn between newer and more established teachers of average class size. However, students in larger classes of newer teachers were more willing to learn than students in smaller classes of newer teachers. In addition, students' reports of their willingness to learn in larger classrooms of more established teachers were less favorable than those in smaller classrooms.

This interaction is an intriguing finding. It is important to remember that the students' perceptions are in regards to overall school climate and not classroom climate, and the factors that contribute to the dynamics of the classroom may affect school climate differently. Students are not randomly assigned to classrooms or teachers; therefore, it is possible that this interaction is indirectly measuring some other construct. Perhaps our measurement of the number of years teaching (i.e., newer vs. more experienced teachers) is a proxy measure for teaching styles or teacher-student interactions that were not measured directly. It is also possible that newer teachers in our study were exposed to different

teaching methods while receiving their education than were their more experienced colleagues.

Other factors could explain why students of different classroom compositions perceive school climate differently. Studies suggest that teachers' perceptions and attitudes toward students affect their own behavior as well as students' behavior within the classroom (Ladd, Birch, & Buhs, 1999; Weinstein, Madison, & Kuklinski, 1995). Osterman (2000) contended that students with a sense of belonging and positive involvement in the classroom are more likely to demonstrate acceptance of authority and regulate their own behavior in the classroom. In addition, teacher interactions with students seem to influence students' perceptions of one another (Birch & Ladd, 1997). Prior research has indicated that teachers who display favoritism or are perceived as not being fair to all students can negatively influence the sense of community (Altenbaugh, Engel, & Martin, 1995). Students' attitudes about their teacher also tend to influence their sense of school satisfaction, such that school satisfaction is higher for students who like their teacher and have a more supportive relationship with the teacher (Baker, 1999; Verkuyten & Thijs, 2002). The current study was not designed to examine process-oriented variables, such as teaching style and teacher-student interaction; therefore, additional research on these types of variables within a multilevel framework is needed. It should also be noted that examining within-level interactions within the multilevel framework is rare. Methodologically, further exploration into these interactions is needed to investigate the validity of the relationship we uncovered.

### *General Discussion*

The results of the current study indicate that student- and classroom-level factors tend to have greater influence on students' perceptions of the school environment than do school-level factors. Interventions aiming to enhance students' perceptions may be most effective if they target those with the most negative attitudes, such as male and minority students. There are several individual-level factors that were not examined in the current study that might also influence students' perceptions, such as their academic abilities, social relationships, socioeconomic status, and own problem behavior. Future research should examine these factors more specifically as possible predictors of school climate that may help target individual interventions more effectively. With regard to school-level factors, there are several initiatives focused on creating smaller schools and learning environments, and our findings suggest that school size was only marginally inversely related to climate. Efforts to increase the connectedness of within-school groupings, such as improving relations between teachers and students and those between peers within classrooms, may have a more favorable impact on students' perceptions of school climate than focusing on efforts to affect school-level factors (e.g., reducing school size). Reducing class size has often been cited as a possible strategy for increasing academic performance; however, our findings, along with those of other climate studies, suggest that class size alone may not greatly influence perceptions of school climate (Griffith, 1995; van der Oord & Van Rossem, 2002; Verkuyten & Thijs, 2002). Taken together, these findings suggest that factors at several levels should be assessed when examining different aspects of school climate and developing initiatives to enhance school climate.

The dynamics of individual and situational interest and academic performance were examined in the college classroom and 7 semesters later in conjunction with achievement goals. At the beginning of an introductory psychology course, participants reported their initial interest in psychology, achievement goals, and situational interest in course lectures. At the end of the semester, participants ( $N = 858$ ) reported their situational interest in course lectures and psychology. In the short term, relationships emerged among initial interest, achievement goals, situational interest, and class performance. Longitudinally, situational interest during the introductory course, independent of initial interest, predicted subsequent course choices. Results are discussed in terms of S. Hidi and K.A. Renninger's (2006) 4-phase model of interest development and the multiple goals model (J. M. Harackiewicz, K. E. Barron, P. R. Pintrich, A. J. Elliot, & T. M. Thrash, 2002).

**Keywords:** achievement goals, interest, achievement motivation, academic motivation, academic performance

One of the critical developmental tasks that students face in college is to identify and solidify their interests as they select courses, choose their academic major, and make decisions about career paths. Why do some students become involved and interested in their coursework, and why do they continue in a particular academic discipline? Do students learn more and perform better in their classes when they are interested? These questions highlight the importance of interest in college education, both as an important outcome variable in its own right (Harackiewicz, Barron, & Elliot, 1998; Hidi & Harackiewicz, 2000; Maehr, 1976) and as a motivational factor that may influence learning and performance (Hidi, 1990; Hidi & Renninger, 2006).

Students' achievement goals may play an important role in shaping academic motivation and interest because they reflect the

purpose of achievement behavior in a particular setting and can influence how a student approaches coursework (Dweck & Leggett, 1988; Nicholls, 1984). When pursuing mastery goals in a learning situation, students want to develop competence by acquiring new knowledge and skills. When pursuing performance-approach goals, students want to demonstrate competence relative to others, and when pursuing performance-avoidance goals, they hope to avoid the demonstration of incompetence (Elliot & Church, 1997; Middleton & Midgley, 1997). In addition to goals focused on competence, some students adopt work-avoidance goals that focus on effort minimization (Brophy, 1983; Nicholls, 1989).

Because students can and do pursue multiple goals in their classes, researchers have begun to examine the independent and interactive effects of these goals on performance and motivation (Harackiewicz et al., 1998; Pintrich, 2000). Although there is little debate about the negative effects of performance-avoidance and work-avoidance goals (e.g., Elliot & Church, 1997; Harackiewicz, Barron, Carter, Lehto, & Elliot, 1997; Middleton & Midgley, 1997), the pattern of mastery and performance-approach goal effects has been mixed on measures of interest and performance (see Harackiewicz, Barron, Pintrich, Elliot, & Thrash, 2002, for review). Several studies have found positive effects of performance-approach goals, but not mastery goals, on grades in high school and college classes (Archer, 1994; Bouffard, Boisvert, Vezeau, & Larouche, 1995; Bouffard, Vezeau, & Bordeleau, 1998; Elliot & Church, 1997). In contrast, several studies have found

positive effects of mastery goals, but not performance goals, on interest in classes. For example, Harackiewicz et al. (1997) found that performance-approach goals predicted higher grades in an introductory psychology class, whereas mastery goals predicted interest in the class.

Harackiewicz, Barron, Tauer, and Elliot (2002) replicated these results and extended the study of goal effects over time by following introductory psychology students until they graduated. Performance-approach goals predicted grades in an introductory psychology class, grades in subsequent psychology classes, and academic GPA over the ensuing semesters. The performance-approach goal effects remained significant even with prior levels of academic performance and standardized measures of ability controlled. In contrast, mastery goals predicted interest in the class, continued interest in psychology, and whether students chose to major in psychology. Considered together, this pattern of findings supports a multiple goal perspective (Barron & Harackiewicz, 2000; Harackiewicz, Barron, Pintrich, et al., 2002; Pintrich, 2000) in which mastery and performance-approach goals can both promote important, but distinct, educational outcomes.

### Reciprocal Effects of Mastery Goals and Interest

The positive associations between mastery goals and interest are well documented (Harackiewicz, Barron, Pintrich, et al., 2002), but the direction of causality has not been examined closely. Previous longitudinal research has tested whether the adoption of mastery goals early in a course is a predictor of subsequent interest (whether measured later in the course or over the course of an undergraduate career) but has not tested whether initial levels of interest (measured at the beginning of a course) predict the adoption of mastery goals. It is important to consider the level of interest in place before students formulate their goals for a course. Students who begin a class with higher levels of initial interest may be more likely to adopt mastery goals because they want to learn more about the domain that interests them. In turn, these mastery goals may promote the continued development of interest, suggesting that mastery goals might actually mediate interest processes. In other words, initial interest might predispose students to adopt mastery goals, which then predict subsequent interest. Although previous goals research has considered mastery goals as predictors of interest (e.g., Harackiewicz et al., 1997; Harackiewicz, Barron, Tauer, Carter, & Elliot, 2000; Harackiewicz, Barron, Tauer, & Elliot, 2002), the reverse direction of causality seems equally plausible: Interest in the course content might predict the adoption of mastery goals because students who are interested in a topic may want to learn more about it (Renninger, 2000).

Another possibility is that initial interest predicts both mastery goal adoption and subsequent interest, and is therefore a third variable that accounts for the mastery goal-subsequent interest relationship. Similar concerns about reverse causality and third-variable explanations for the relationship between performance-approach goals and course grades have been addressed in previous research by including measures of prior academic performance and standardized ability tests (e.g., Harackiewicz, Barron, Tauer, & Elliot, 2002), but these issues have not been addressed with respect to mastery goal effects on interest. Only by measuring initial interest before goal adoption will it be possible to disentangle

some of these intriguing possibilities and explore the reciprocal effects of mastery goals and interest.

### The Development of Interest

A careful examination of interest development requires consideration of the interests and experience that students bring to class, as well as the types of interest that can develop or deepen in classes over time. Some students may enter a course with a high level of interest in the topic because they have had prior experience with related material and have found it interesting. These students' interest might deepen and solidify over the course of a semester. Other students may begin a course with limited knowledge and little initial interest in the topic but discover or develop interest during the course depending on features of the course, such as whether the instructor or course materials stimulate their attention and involvement. This highlights the two different types of interest discussed in the literature. Interest that resides within the individual over time has been distinguished from interest that emerges in response to situational cues. The first type has been labeled *individual interest*; it has a dispositional quality and is deep and enduring. Renninger (2000) argued that individual interest requires having substantial knowledge of a topic as well as valuing that knowledge. Students who enter a course with a high level of initial interest in the topic may be described as having an individual interest. The second type has been labeled *situational interest*; it emerges spontaneously in response to features of the environment (Dewey, 1913; Hidi, 1990).

Hidi and Baird (1986) raised an important distinction between two types of situational interest, reflecting the process through which situational interest is first triggered and then maintained in a particular situation. Situational factors such as instructional style or collative variables can first trigger or "catch" interest through attentional and affective processes, but once situational interest is aroused, it may or may not last, depending on the external supports in the situation (Hidi & Renninger, 2006; Mitchell, 1993). In a college classroom, for example, an entertaining lecture might stimulate students' attention and catch their interest, but course material that is personally meaningful or valued may better hold students' interest (Harackiewicz et al., 2000; Malone & Lepper, 1987; Rathunde, 1993; Schiefele, 1991; Wigfield & Eccles, 1992). If classroom factors promote the development of meaning and value, situational interest may be maintained over time. If this maintained interest endures beyond the particular situation and is associated with the accumulation of knowledge about the topic, it may eventually become a deep, individual interest (Hidi & Renninger, 2006; Krapp, 2002). Therefore, it is also important to distinguish two types of situational interest: "caught" interest (associated with arousal, attention, and affect) and "held" interest (associated with personal value and meaning).

Our research concerns the interest (both individual and situational) that can develop or deepen over the course of an introductory college course, taking initial levels of interest into account. Students might come to an introductory class with a well-developed individual interest (indeed, they may have chosen to take that class because of their prior knowledge and valuing of the course content), and their individual interest may deepen if they find value or personal meaning in the course material. In contrast, for students who begin the class without strong interest, the de-

velopment of interest must begin with situational interest. Because situational interest is externally supported, students who begin a class without much interest in the domain will only develop interest if features of the class trigger or catch their situational interest (Hidi & Renninger, 2006). This situational interest may be maintained or held if students come to find meaning in the course material.

The experiences students have during an introductory course may promote continuing interest that has the potential to develop into a deeper individual interest. For example, students who enter a course with high initial interest may become motivated to take more courses in that content area not only because of their ongoing individual interest, but also because they have come to appreciate the content even more as a consequence of taking the course. Students who begin a course with low initial interest may also develop continuing interest and pursue further coursework in the content area if their situational interest can be held over time. Held situational interest may eventually develop into individual interest if it is accompanied by deepening knowledge and sustained over time and across contexts (Hidi & Renninger, 2006).

### The Current Research

In the present research we examined the development of interest in an academic domain using an achievement goal paradigm. We studied a sample of students in an introductory psychology course, allowing us to examine their initial interest, background knowledge, and goals in a foundational course. This design extends previous research in several ways, most notably by including multiple measures of interest (both individual and situational) and by situating these measures in a temporal sequence relative to the assessment of achievement goals and in relation to students' receipt of performance feedback in the course. Previous research in college courses has only measured situational interest late in the semester, after students have received extensive performance feedback, making it impossible to disentangle interest-performance relations. In the present study we included an early measure of situational interest ("catch-1"), administered before any exams were given, allowing us to test situational interest as an uncontaminated predictor of performance. In addition, we obtained students' grades on the first exam in the course, which allowed us to examine the effects of early performance on the subsequent development of situational interest (both "catch-2" and "hold") measured later in the course. Thus, in addition to measuring initial interest, the current study included a measure of situational interest that was uncontaminated by performance feedback, as well as an early indicator of performance, allowing us to test the reciprocal relations between interest and performance across the semester.

We had three primary objectives for the current research. First, we wanted to integrate goal theory (Pintrich, 2002) with interest theory (Hidi & Renninger, 2006) by examining the role of individual interest and mastery goals in promoting the development of situational and continuing interest in an academic domain. We hypothesized that initial interest would directly predict students' adoption of mastery goals, situational interest, and continued interest. Some students are drawn to courses because they have initial interest in the topic. Once in the course, these students should want to learn more about the topic (adopt mastery goals) because interest directly influences the desire to gain knowledge

about the domain (Renninger, 2000). The course should further expose these individuals to the content so that their initial interest may continue to deepen. However, we also hypothesized that mastery goals would promote students' situational and continuing interest independent of initial interest. A mastery goal orientation may lead students to approach their coursework in a task-focused manner that allows them to become excited about and involved in the learning experience. Mastery goals may therefore be particularly effective in facilitating the triggering of situational interest, which when combined with personal meaning and/or value may develop further into a held situational interest. Thus, individual interest and mastery goals may represent related but relatively distinct paths to the development of situational and continued interest.

Our second objective was to examine the reciprocal relations between interest and performance in a classroom context. Hidi (1990) has argued that interest can promote performance, but in previous classroom studies, interest measures have only been collected late in the course, after students have received considerable performance feedback (e.g., Harackiewicz et al., 1997), making it difficult to test this hypothesis. In the current study, we collected a measure of situational interest before any exams were administered in the course, enabling us to examine the effect of situational interest on later performance. Also, because we obtained an early measure of performance and later measures of situational interest, it was possible to test the effects of performance on later interest. Our design therefore allowed us to test both possibilities simultaneously. Accordingly, we hypothesized that students who reported situational interest would perform better in the class, and we also predicted that students who performed well on early exams would develop interest in the class.

Our third objective was to examine the predictors of goal adoption. We have already discussed our prediction that initial interest should predict mastery goal adoption, but it is important to compare initial interest with other variables that have been shown to predict achievement goal adoption in previous research. Harackiewicz et al. (1997; Harackiewicz, Barron, Tauer, & Elliot, 2002) found that students who were high in workmastery, one component of achievement motivation identified by Spence and Helmreich (1983), were particularly likely to adopt mastery goals and reject work-avoidance goals, whereas students high in competitiveness (a second component of achievement motivation) were more likely to adopt performance-approach goals. Of particular interest in the current study was whether this pattern would be replicated when we controlled for the effects of initial interest. If both initial interest and workmastery predict students' adoption of mastery goals, then we will have identified two independent predictors of mastery goals, one that taps an individual's response to the specific course content (initial interest) and one that taps an individual's characteristic response to achievement situations (workmastery).

We situated the present analyses of interest processes and goal adoption within the context of our previous goals research. We expected to replicate both the short-term and long-term goal effects documented by Harackiewicz et al. (1997, 2000; Harackiewicz, Barron, Tauer, & Elliot, 2002) and Elliot and Church (1997). Specifically, we hypothesized that performance-approach goals would positively predict grades; that work-avoidance and performance-avoidance goals would negatively predict grades; and that mastery goals and initial interest would both predict situa-

tional interest, continued interest over the following seven semesters, and whether students chose to major in psychology. Finally, we hypothesized that the effects of goals and initial interest on long-term outcomes would be mediated through their impact on short-term outcomes. Specifically, we expected mastery goals and initial interest to predict continued interest in psychology and majoring in psychology because they promote the development of held situational interest in the topics covered in the introductory course.

## Method

### Overview

In a prospective, longitudinal study, we collected data at five points in time from students enrolled in introductory psychology courses at a large midwestern university. The first four assessments were during the semester that students were enrolled in Introductory Psychology, and for the fifth assessment, we obtained data from students' academic records seven semesters later. During the first week of the semester (Time 1), we measured students' initial interest in psychology, as well as individual differences in achievement orientation. During the third week of the semester (Time 2), before any exams or feedback, we measured students' achievement goals for Introductory Psychology as well as their enjoyment of the course at that point (catch-1). Two weeks before the end of the semester (Time 3), we measured students' enjoyment of the class (catch-2) and their valuation of the course material (hold). Upon completion of the semester (Time 4), we obtained students' final grade in Introductory Psychology as well as their overall semester GPA. Finally, seven semesters after the completion of the introductory course (Time 5), we obtained students' transcripts and coded them for continued interest in psychology, majoring in psychology, grades in subsequent psychology classes, and overall GPA.

### Participants and Setting

We recruited students from five classes of Introductory Psychology (approximately 430 students per class). Only students who were taking the course for graded credit while pursuing an undergraduate degree were included. This excluded, for example, undergraduate students who were taking the course for pass/fail credit as well as graduate students. Classes were almost entirely lecture format. Students took three or four multiple-choice exams (the number of exams varied across classes), and final grades were based on a normative curve recommended by the psychology department.

Data collection at Time 1 was part of a large departmental survey (1,265 participants) for which Introductory Psychology students received extra credit in exchange for their participation. Participants enrolled in our study at Time 2, when they signed consent forms and authorized access to their academic records. Students completed questionnaires during class time and did not receive extra credit for participation in the remainder of the study. Of the original 1,265, 1,128 participants entered the study at Time 2. After enrollment in the study, some attrition occurred over subsequent assessments. First, 27 participants dropped the course before the semester ended (course drops). Second, because data

were collected during class time, students absent from class at Time 3 ( $n = 206$ ) were not included in the study (absentee drops). Finally, 37 participants took fewer than 15 additional credits over the following seven semesters (equivalent to one full-time semester), which precluded coding of long-term follow-up measures (university drops). Thus, the final sample (used in all data analyses unless otherwise noted) included 858 students (279 men, 579 women) and represented 76% of the students who enrolled in our study at Time 2.

### Time 1: Initial Interest and Achievement Orientation

During the first week of the semester, students completed a questionnaire about their interest and background in psychology. All items were rated on a 7-point scale (1 = *not at all true of me*, 7 = *very true of me*). Seven items assessed initial interest in psychology, and three items measured students' previous experience in psychology (background knowledge). We based items on those used by Barron and Harackiewicz (2003) and wrote new items to represent Renninger's (1992) conceptualization of individual interest. Items and reliabilities for all scales are presented in the Appendix.

Participants also completed the Work and Family Orientation Questionnaire (Helmreich & Spence, 1978; Spence & Helmreich, 1983). This personality measure assesses individual differences in three components of achievement motivation: work orientation, mastery orientation, and competitiveness. Each item was rated on a 5-point scale (1 = *strongly disagree*, 5 = *strongly agree*). The work and mastery items were combined into a single index as recommended by Spence and Helmreich, resulting in a two-dimensional measure of achievement orientation: workmastery and competitiveness. These scales have been shown to have good reliability and validity (Helmreich & Spence, 1978; Spence, Pred, & Helmreich, 1989).

### Time 2: Achievement Goals and Situational Interest

Three weeks into the semester, students completed questions about their achievement and work-avoidance goals. All items were rated on a 7-point scale (1 = *not at all true of me*, 7 = *very true of me*) and referred to their current goal orientation in Introductory Psychology. Four different types of goals were assessed: mastery, performance-approach, performance-avoidance, and work-avoidance. Scales were adapted from those used by Harackiewicz et al. (1997), Elliot and Church (1997), Midgley et al. (1996), and Pintrich (Pintrich & DeGroot, 1990; Pintrich & Garcia, 1991).

After completing questions about their goal orientations, students were asked to focus on their reactions to the class and to report their situational interest (catch-1). Participants responded to questions about their experiences in and enjoyment of course lectures on a 7-point scale (1 = *strongly disagree*, 7 = *strongly agree*). Items were adapted from Harackiewicz et al. (2000; Harackiewicz, Barron, Tauer, & Elliot, 2002) to assess the catch component of situational interest, based on Hidi's theoretical work (Hidi & Baird, 1986; Hidi & Berndorff, 1998).

### Time 3: Interest

Near the end of the semester (13 weeks into the term, with only 2 weeks remaining), students responded to questions about their

interest in the course. All items were rated on a 7-point scale (1 = *strongly disagree*, 7 = *strongly agree*). Five items assessed students' affective reactions to course lectures (catch-2), similar to the measure at Time 2. Nine other items assessed students' feelings about and personal valuing of the course material (hold; Krapp, 2002; Schiefele, 1991). Linnenbrink-Garcia et al. (2007) conducted exploratory and confirmatory factor analyses with these items and demonstrated that catch and hold represented separate components of situational interest.

#### *Time 4: Performance in Introductory Psychology and Semester GPA*

We obtained measures of students' performance in Introductory Psychology, which consisted of students' scores on the first exam in the course (first exam score), as well as their overall final grade (final grade). Because different scales were used by each instructor for the first exam, we standardized first exam scores within each section of the course. In contrast, final grades were assigned using the same letter-grade scale for all sections and were distributed similarly within sections. Based on a 4-point scale ( $A = 4.0$ ,  $F = 0.0$ ), the mean grade for students in our study was 2.99 ( $SD = 0.79$ ). Grades were distributed as follows:  $A = 22.6\%$ ,  $AB = 19.5\%$ ,  $B = 19.3\%$ ,  $BC = 16.3\%$ ,  $C = 19.6\%$ ,  $D = 2.7\%$ ,  $F = 0\%$ . We also obtained students' overall semester GPA for the semester in which they took Introductory Psychology.

#### *Time 5: Continued Interest and Subsequent Performance*

Seven semesters later, we obtained students' academic records and used them to compute four long-term outcome measures. First, we counted the number of additional psychology course credits students had taken over the years, providing a behavioral measure of continued interest in psychology (psychology courses taken). The mean number of additional psychology credits taken was 5.23 ( $SD = 10.32$ ), with the typical psychology course at this university worth 3 credits. We also recorded whether students had declared a major yet and, if so, whether they had majored in psychology (psychology major).

We also calculated two long-term performance measures. To measure academic performance in subsequent psychology courses, we computed a psychology GPA for those students who had taken additional psychology classes (psychology GPA). Finally, as a general measure of academic performance, we also computed a GPA for all courses taken after the semester of the initial study (subsequent GPA).

## Results

### *Attrition Analyses*

Three sets of attrition analyses were conducted comparing the final sample to (a) participants who dropped the course (course drops;  $n = 27$ ), (b) participants who were not in class at Time 3 (absentee drops;  $n = 206$ ), and (c) participants who completed the study but did not enroll in enough subsequent courses for inclusion in analyses on long-term follow-up measures (university drops;  $n = 37$ ). Comparisons were made on all variables allowed by the patterns of missing data for each group.

The group of students who dropped the course (course drops) were compared with the final sample on all Time 1 and Time 2 variables. Independent sample  $t$  tests revealed four significant differences. Effect sizes (Cohen's  $d$ ) were computed for these differences, revealing moderate effects. The final sample had higher scores on workmastery,  $t(883) = 2.00$ ,  $p < .05$ ,  $d = .39$ ; and mastery goals,  $t(883) = 2.56$ ,  $p < .05$ ,  $d = .50$ ; and lower scores on performance-avoidance goals,  $t(883) = -2.31$ ,  $p < .05$ ,  $d = -.45$ ; and work-avoidance goals,  $t(883) = -2.84$ ,  $p < .01$ ,  $d = -.56$ . No differences emerged for initial interest, background knowledge, competitiveness, performance-approach goals, or catch-1.

We then compared students who were absent for Time 3 (absentee drops) with the final sample on all Time 1 and Time 2 variables and on final grade. Independent sample  $t$  tests revealed five significant differences. There were small effects showing that the final sample was higher on initial interest,  $t(1062) = 2.34$ ,  $p < .05$ ,  $d = .18$ ; workmastery,  $t(1062) = 3.12$ ,  $p < .01$ ,  $d = .24$ ; and mastery goals,  $t(1062) = 2.51$ ,  $p < .05$ ,  $d = .19$ ; and lower on work-avoidance goals,  $t(1062) = -2.89$ ,  $p < .01$ ,  $d = -.22$ . The final sample also had higher final grades, revealing a moderate effect,  $t(1062) = 7.53$ ,  $p < .01$ ,  $d = .59$ . No reliable differences emerged for background knowledge, competitiveness, performance-approach goals, performance-avoidance goals, or catch-1.

Finally, we compared the final sample to the group of university drops on all variables from Times 1 to 4. Two significant differences emerged. The final sample received higher grades,  $t(893) = 3.10$ ,  $p < .01$ ,  $d = .52$ , and was lower in work-avoidance goals,  $t(893) = -1.96$ ,  $p = .05$ ,  $d = -.33$ , than the university drops. Considered together, these results suggest that students who expressed initial interest, adopted mastery goals, or achieved higher grades were somewhat overrepresented in our sample, whereas students who adopted performance-avoidance and work-avoidance goals were somewhat underrepresented.

### *Descriptive Statistics and Factor Analyses*

The means and standard deviations for all variables are reported in Table 1 along with the zero-order intercorrelations. Although the structure, content, and grading distributions of the five class sections were comparable, we tested for instructor differences in all variables. There were significant instructor effects on several variables, indicating that students reported higher levels of some goals and types of interest in some sections compared with others. Therefore, we included four dummy code terms (D1–D4) to test and control for mean-level differences between the instructors in all subsequent analyses. One class was arbitrarily designated as the control group (Cohen & Cohen, 1983).

We conducted an exploratory factor analysis of our goal and interest measures that were collected at Time 2 to document the difference between goals and situational interest. There were 20 items, and we used principal components extraction with oblimin rotation to determine their structure. There were five eigenvalues greater than 1.0, accounting for 70% of the total item variance. Moreover, the pattern matrix evidenced simple structure that corresponded to the five predicted factors (catch-1, mastery goal, performance-approach goal, performance-avoidance goal, work-avoidance goal). Items loaded on their intended factors (none

\*  $p < .01$ .

lower than .57) and did not load on their unintended factors (none higher than .27).

We also conducted a factor analysis of all of our interest and goal measures (41 items) across Times 1 through 3 using the same procedure. We found that there were eight eigenvalues greater than 1.0, accounting for 70% of the variance. The pattern matrix again revealed simple structure, with the eight factors corresponding to our eight predicted factors (the five factors in the previous analysis with the addition of individual interest, catch-2, and hold), with each item loading on its intended factor (no loadings lower than .52) and not loading on unintended factors (no loadings higher than .30). These factor analyses indicated that the items were measuring separate constructs.

### Regression Models

We ran three sets of regression analyses, each predicting outcomes measured at different time points. We conducted one series of multiple regression analyses to examine the predictors of the achievement goals adopted in the class (Time 1 variables predicting Time 2 variables), a second series to examine the predictors of short-term outcome variables measured during the semester in which students took Introductory Psychology (Time 1 and 2 variables predicting Time 3 and 4 variables), and a final series to examine the predictors of long-term outcome variables collected in the follow-up assessment (Time 1, 2, 3, and 4 variables predicting Time 5 variables).

This data analytic strategy allowed us to retain the continuous nature of the variables and to test the independent effects of each predictor variable as well as the interactions between them. For the following analyses, all continuous main effect terms were standardized, and multiplicative two- and three-way interaction terms were created with these variables (Aiken & West, 1991). Interactions that were significant on any measure were retained in all models, but nonsignificant interactions were trimmed from models. We also retained the Mastery  $\times$  Performance-Approach Goal interaction in all models, because this represents one important test of the multiple goal perspective (Barron & Harackiewicz, 2001). To interpret significant interaction effects from these analyses, we computed predicted values ( $\hat{Y}$ s) for representative high and low

groups (1 *SD* above and below the mean) from the regression equations using the unstandardized regression coefficients. Because of the large sample size, statistical power was high. Therefore, we set alpha at .01 and only interpreted standardized regression coefficients that were .10 or greater.

### Predictors of Achievement Goals

Our first series of multiple regression analyses examined the effects of initial interest and achievement orientation on goals adopted in the classroom. Preliminary regression models included the main effect terms for initial interest, background knowledge, workmastery, competitiveness, gender (coded +1 for women and -1 for men), the four instructor dummy codes, as well as all two- and three-way interactions among these variables. No interactions were significant, but the Initial Interest  $\times$  Background interaction was retained for consistency with other models, resulting in a 10-term goals model. Table 2 summarizes each of the models we tested.

**Mastery goals.** The overall model was significant,  $F(10, 847) = 54.56, p < .001 (R^2 = .39)$ . Main effects were found for initial interest,  $F(1, 847) = 274.88, p < .001 (\beta = .48)$ ; workmastery,  $F(1, 847) = 90.13, p < .001 (\beta = .27)$ ; and competitiveness,  $F(1, 847) = 17.62, p < .001 (\beta = -.12)$ . Students high in initial interest, those high in workmastery, or those low in competitiveness were more likely to adopt mastery goals. In addition, one of the instructor dummy code contrasts (D3) was significant,  $F(1, 847) = 7.89, p < .01 (\beta = .10)$ , indicating a significant difference between two classes in mastery goal adoption.

**Performance-approach goals.** The overall model was significant,  $F(10, 847) = 16.38, p < .001 (R^2 = .16)$ . The main effect of competitiveness was significant,  $F(1, 847) = 131.54, p < .001 (\beta = .38)$ , and showed that students high in competitiveness were more likely to adopt performance-approach goals. In addition, one of the instructor dummy code contrasts (D2) was significant,  $F(1, 847) = 7.06, p < .01 (\beta = -.11)$ , indicating a difference between two classes in the extent to which students adopted performance-approach goals.

Table 2  
Regression Models Tested (Predictor Variables Included in Each Model)

Goals model (10 terms)
Initial interest; background; Initial Interest $\times$ Background interaction; workmastery; competitiveness; gender; dummy codes (4)
Dependent variables: mastery, performance-approach, performance-avoidance, and work-avoidance goals
Basic short-term model (15 terms)
Goals model with the addition of mastery, performance-approach, performance-avoidance, and work-avoidance goals; Mastery $\times$ Performance-Approach interaction
Dependent variables: catch-1; catch-2; hold; final grade
Catch-1 short-term model (16 terms)
Basic short-term model with the addition of catch-1
Dependent variables: catch-2; hold; final grade
Direct effects long-term model (16 terms)
Basic short-term model with the addition of number of credits taken
Dependent variables: psychology credits taken; psychology major; psychology GPA
Final long-term model (21 terms)
Direct effects long-term model with the addition of catch-1; catch-2; hold; final grade; and Hold $\times$ Grade interaction
Dependent variables: psychology credits taken; psychology major; psychology GPA

Note. The number of terms that were retained in each specific model after preliminary testing of higher order interactions appear in parentheses.

**Performance-avoidance goals.** The overall model was significant,  $F(10, 847) = 9.20, p < .001$  ( $R^2 = .10$ ); and the main effects of initial interest,  $F(1, 847) = 17.58, p < .001$  ( $\beta = -.15$ ); workmastery,  $F(1, 847) = 37.65, p < .001$  ( $\beta = -.21$ ); and competitiveness,  $F(1, 847) = 29.45, p < .001$  ( $\beta = .19$ ), were significant. Students high in initial interest or workmastery were less likely to endorse performance-avoidance goals. In contrast, students high in competitiveness were more likely to endorse performance-avoidance goals.

**Work-avoidance goals.** The overall model was significant,  $F(10, 847) = 28.14, p < .001$  ( $R^2 = .25$ ); and the main effects of initial interest,  $F(1, 847) = 33.69$  ( $\beta = -.19$ ); workmastery,  $F(1, 847) = 85.53, p < .001$  ( $\beta = -.29$ ),  $p < .001$ ; competitiveness,  $F(1, 847) = 33.49, p < .01$  ( $\beta = .18$ ); and gender,  $F(1, 847) = 19.98, p < .001$  ( $\beta = -.14$ ), were significant. Students high in initial interest or workmastery were less likely to endorse work-avoidance goals. Competitive students and male students were more likely to endorse work-avoidance goals. In addition, three of the instructor dummy code contrasts (D2, D3, and D4) were significant,  $F(1, 847) = 19.78, p < .001$  ( $\beta = -.17$ );  $F(1, 847) = 10.23, p < .01$  ( $\beta = -.12$ ); and  $F(1, 847) = 9.97, p < .01$  ( $\beta = -.13$ ), respectively, indicating that students in certain classes were more likely to adopt work-avoidance goals than those in other classes. Figure 1 depicts the significant paths from Time 1 variables to all four goals.

### Predictors of Short-Term Outcomes

**Regression model for short-term analyses.** In our second series of multiple regression analyses, we tested the short-term effects of initial interest, achievement orientation, and achievement goals on catch-1, catch-2, hold, and final grade. Preliminary models included the main effects of initial interest; background knowledge; workmastery; competitiveness; gender; the four in-

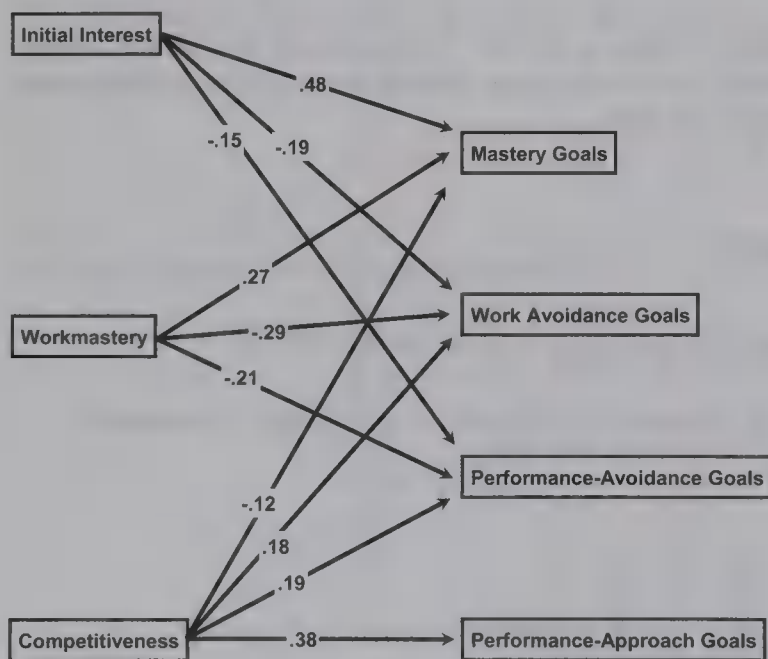

Figure 1. Predictors of achievement goals. All paths represented are significant ( $p < .01$ ). Path coefficients are standardized regression coefficients. For clarity of presentation, significant gender and instructor effects are not depicted, but these variables were controlled in these analyses.

structor dummy codes; mastery, performance-approach, performance-avoidance, and work-avoidance goals, as well as all two- and three-way interactions among these variables. Preliminary analyses revealed no significant higher order interactions, and thus the only interaction terms retained were those between initial interest and background knowledge, and between mastery and performance-approach goals. We therefore tested a 15-term basic short-term model (see Table 2).

**Catch-1.** The basic short-term model was significant,  $F(15, 842) = 21.08, p < .001$  ( $R^2 = .27$ ). A significant main effect was found for mastery goals,  $F(1, 842) = 53.06, p < .001$  ( $\beta = .29$ ), such that students who strongly endorsed mastery goals reported higher levels of interest in the lectures at Time 2 than students who did not endorse mastery goals. A significant main effect for work-avoidance goals,  $F(1, 842) = 10.70, p < .01$  ( $\beta = -.12$ ), showed that students who endorsed work-avoidance goals reported less interest in the lectures. A significant effect of one of the instructor codes (D3),  $F(1, 842) = 21.20, p < .001$  ( $\beta = .18$ ), indicated a difference between two sections in the extent to which students reported catch-1. Figure 2 depicts a path model of these effects.

We tested the predictors of catch-2, hold, and final grade in two steps. We first tested the basic 15-term model described previously, and then, because catch-1 was measured 2 months earlier than these three short-term outcome variables, we were also able to test for the effects of early situational interest. We therefore tested a second model in which catch-1 was included as a predictor of the later variables. Preliminary testing revealed no significant interactions of catch-1 with the terms included in the basic model, and thus the catch-1 short-term model included 16 terms comprising the basic model plus the inclusion of catch-1 (see Table 2). Figure 2 depicts the paths to the three short-term variables (catch-2, hold, and final grade) estimated from the catch-1 short-term model.

**Catch-2.** The basic short-term model was significant,  $F(15, 842) = 15.05, p < .001$  ( $R^2 = .21$ ). A significant main effect was found for mastery goals,  $F(1, 842) = 33.64, p < .001$  ( $\beta = .24$ ), such that students who adopted mastery goals reported higher levels of interest in the lectures at Time 3 than students who did not endorse mastery goals. In addition, two of the instructor dummy code terms (D3 and D4) were significant,  $F(1, 842) = 33.09, p < .001$  ( $\beta = .24$ ), and  $F(1, 842) = 7.03, p < .01$  ( $\beta = .10$ ), indicating that students in certain classes were more likely to report higher levels of catch-2 than those in other classes.

The catch-1 short-term model accounted for significantly more variance in catch-2 than the basic model ( $R^2_{\text{change}} = .21, p < .001$ ). This change was attributable to the significant effect of catch-1,  $F(1, 841) = 296.70, p < .001$  ( $\beta = .53$ ), suggesting that students who reported catch at Time 2 were more likely to report catch at Time 3 (see Figure 2). The effect of mastery goals was no longer significant ( $\beta = .09$ ). Following the procedures outlined by Kenny, Kashy, and Bolger (1998), we conducted a formal test of mediation and found that the effect of mastery goals on catch-2 was significantly mediated through catch-1 ( $z = 6.65, p < .01$ ). Figure 3 depicts this mediation analysis.

**Hold.** The basic short-term model was significant,  $F(15, 842) = 44.31, p < .001$  ( $R^2 = .44$ ). There was a significant main effect of initial interest,  $F(1, 842) = 164.61, p < .001$  ( $\beta = .42$ ), indicating that students who entered the class with a high level of interest reported higher levels of hold. A significant main effect of

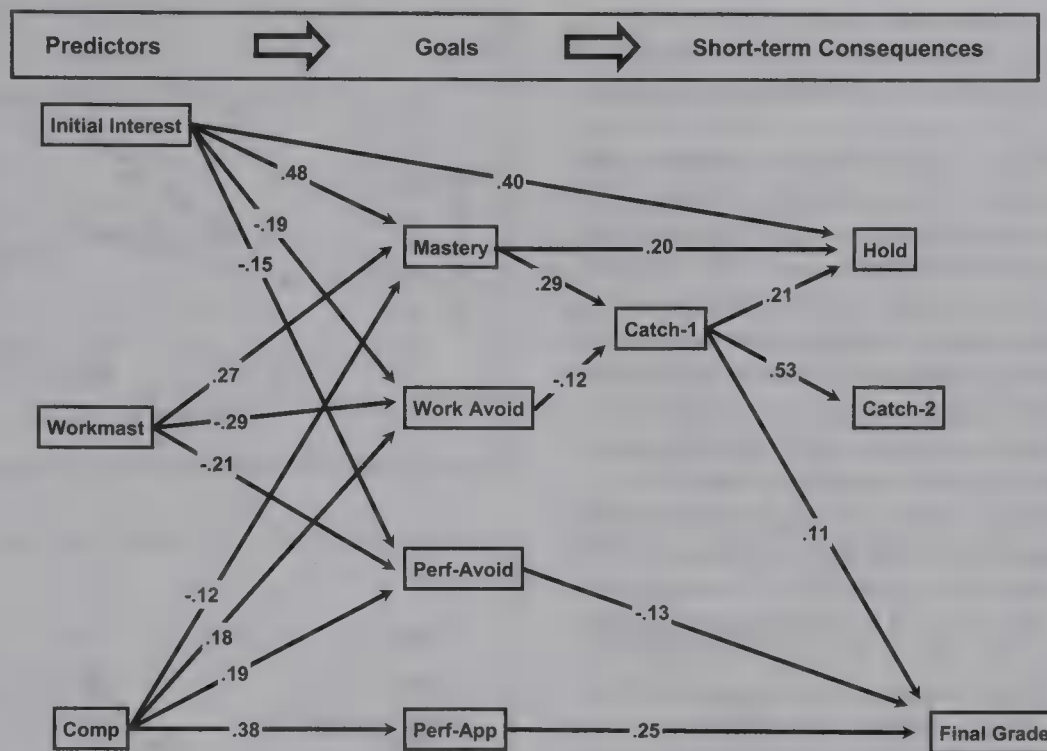

Figure 2. Predictors of short-term consequences. All paths represented are significant ( $p < .01$ ). Path coefficients are standardized regression coefficients. For clarity of presentation, this figure does not show the effects of gender on goal adoption, because gender had no additional effects over time. Instructor effects are not shown in this model, but both gender and instructor effects were controlled for in the model depicted. Workmastery = workmastery; Comp = competitiveness; Mastery = mastery goals; Perf-Avoid = performance-avoidance goals; Perf-App = performance-approach goals; Work Avoid = work-avoidance goals.

mastery goals,  $F(1, 842) = 57.08, p < .001$  ( $\beta = .26$ ), indicated that individuals who had adopted mastery goals early in the semester also reported that they found psychology meaningful and interesting at the end of the semester.

The catch-1 short-term model accounted for significantly more variance than the basic short-term model ( $R^2_{\text{change}} = .03, p < .001$ ), revealing that the effect of catch-1 was significant,  $F(1, 841) = 48.56, p < .001$  ( $\beta = .21$ ). Students who reported catch at Time 2 were more likely to report hold at Time 3. The effects of initial interest and mastery goals remained significant ( $\beta$ s = .40 and .20, respectively). The direct effect of mastery goals was reduced in magnitude, and a formal test of mediation indicated that the effect of mastery goals was significantly mediated through catch-1 ( $z =$

5.01,  $p < .01$ ; see Figure 3). Considered together, these results suggest that catch, initial interest, and mastery goals were all unique contributors to students' interest (hold) at the end of the course (see Figure 2).

**Final grade.** The basic short-term model was significant,  $F(15, 842) = 5.70, p < .001$  ( $R^2 = .09$ ); and there were significant main effects of performance-approach goals,  $F(1, 842) = 45.61, p < .001$  ( $\beta = .25$ ); and performance-avoidance goals,  $F(1, 842) = 14.33, p < .001$  ( $\beta = -.14$ ). Students who adopted performance-approach goals achieved higher grades in their introductory psychology course, and students who adopted performance-avoidance goals earned lower grades.

The catch-1 short-term model accounted for significantly more variance than the basic model ( $R^2_{\text{change}} = .01, p < .01$ ). This was due to the significant effect of catch-1,  $F(1, 841) = 8.39, p < .01$  ( $\beta = .11$ ), indicating that, as predicted, students who reported higher levels of catch-1 attained higher grades in the class. The effects of performance-approach and performance-avoidance goals remained significant ( $\beta$ s = .25 and -.13, respectively). These results are depicted in Figure 2.

### Predictors of Long-Term Outcomes

**Regression models for long-term analyses.** In this series of multiple regression analyses, we tested long-term effects in two steps. First, to investigate the direct effects of initial interest, achievement orientation, and goals on the long-term outcomes, we used the 15-term basic model established in the short-term analyses to predict psychology courses taken, major, and psychology GPA. However, because of the great variability in the total number

Figure 3. Mediation of catch-2 and hold by catch-1. Schematic diagram showing mediated effects, with direct paths from the original basic short-term model shown in parentheses. The path from mastery goals to catch-2 was no longer significant in the catch-1 short-term model, but the path from mastery goals to hold remained significant.

of academic credits taken over this time period ( $M = 79.41$ ,  $SD = 18.04$ ), we also controlled for total number of credits taken in all analyses, resulting in a 16-term direct effects long-term model (see Table 2).

Second, to examine the long-term effects in the context of the short-term effects documented earlier, we added the short-term outcome measures to the direct effects long-term model to test for mediated or indirect effects. Specifically, we added catch-1, catch-2, hold, and final grade to the direct effects model. In addition, we tested the six two-way interactions between catch-1, catch-2, hold, and final grade, but preliminary testing revealed that only the Hold  $\times$  Grade interaction was significant on any measure, and thus the other interactions were trimmed from the model, resulting in a 21-term final long-term model (see Table 2).

**Direct effects on psychology courses taken.** The direct effects long-term model was significant,  $F(16, 841) = 9.58$ ,  $p < .001$  ( $R^2 = .15$ ). There was a significant main effect of initial interest,  $F(1, 841) = 27.82$ ,  $p < .001$  ( $\beta = .21$ ); a significant main effect of background knowledge,  $F(1, 841) = 12.21$ ,  $p < .01$  ( $\beta = .12$ ); and a significant interaction between initial interest and background knowledge,  $F(1, 841) = 12.46$ ,  $p < .001$  ( $\beta = .11$ ). Students who entered the class with higher levels of initial interest were more likely to take more psychology classes if they also had more background in psychology before they took the course ( $\hat{Y} = 10.18$ ), compared to students who did not have much background ( $\hat{Y} = 5.37$ ), and relative to students low in initial interest with high ( $\hat{Y} = 3.41$ ) or low ( $\hat{Y} = 3.48$ ) background knowledge. This interaction is graphed in Figure 4A.

**Mediated and indirect effects on psychology courses taken.** The final long-term model, which included the short-term outcomes, was significant,  $F(21, 836) = 9.02$ ,  $p < .001$  ( $R^2 = .19$ ), and accounted for significantly more variance than the direct effects long-term model,  $F(5, 836) = 6.24$ ,  $p < .001$ . In this model, the main effect of hold was significant,  $F(1, 836) = 14.92$ ,  $p < .001$  ( $\beta = .20$ ). However, the effect of initial interest was reduced in size ( $\beta = .13$ , from .21 in the direct effects model), and a formal test of mediation revealed that the initial interest effect was partially mediated through hold ( $z = 3.67$ ,  $p < .01$ ). The interaction between initial interest and background knowledge remained significant ( $\beta = .11$ ). Finally, the interaction between hold and final grade was significant,  $F(1, 836) = 11.68$ ,  $p < .01$  ( $\beta = .11$ ), indicating that students took more psychology classes when they were high in hold and had high grades in their introductory course ( $\hat{Y} = 9.08$ ) relative to students high in hold with low grades ( $\hat{Y} = 6.27$ ) and relative to students low in hold with either high ( $\hat{Y} = 2.87$ ) or low ( $\hat{Y} = 4.39$ ) grades. This interaction is graphed in Figure 5A. Figure 6 depicts the paths to the three long-term variables (courses taken, psychology major, and psychology GPA) estimated from the final long-term model.

**Direct effects on psychology major.** For these analyses, our sample was limited to the 770 students who had declared majors during their academic careers. Although logistic regression is the most appropriate analysis for a dichotomous measure such as majoring (or not) in psychology, Rosenthal and Rosnow (1991) noted that multiple regression procedures yield accurate results for dichotomous dependent variables as long as the sample size is large and the split between the occurrences of each dichotomous outcome is not extreme (as was the case here). For consistency with the rest of the Results section, we report multiple regression

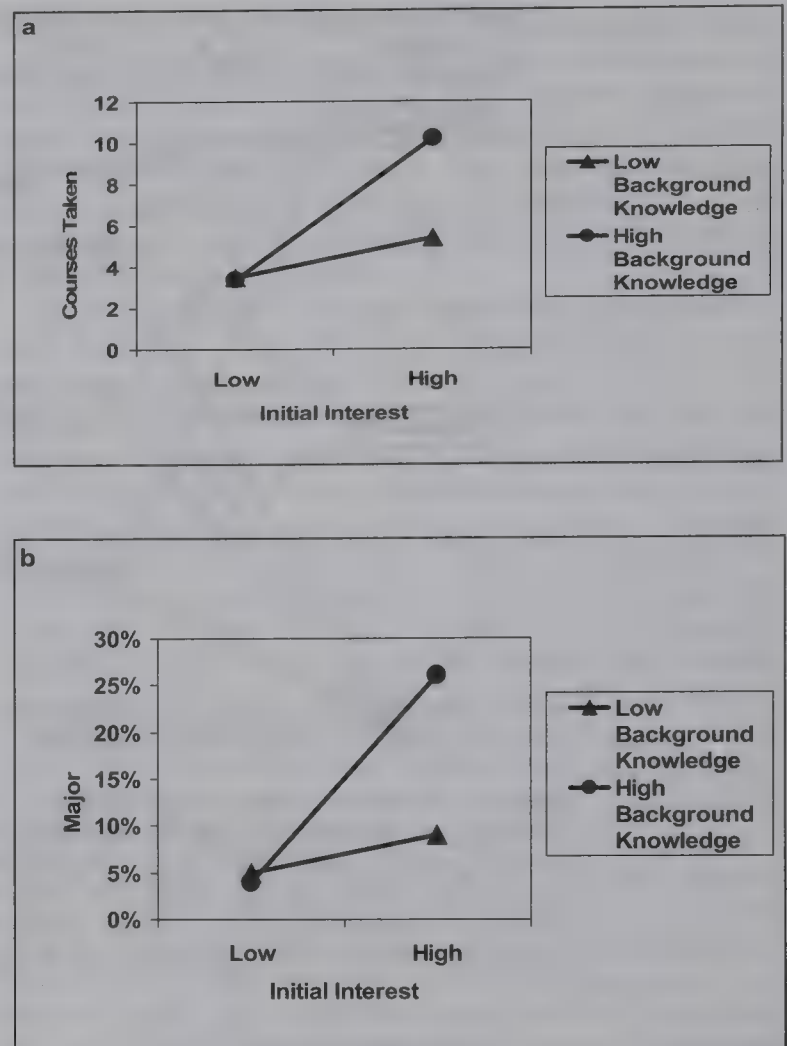

Figure 4. Predicted values for Initial Interest  $\times$  Background Knowledge interactions for courses taken (A) and for majoring in psychology (B). We computed predicted values for representative high and low groups (1 SD above and below the mean) for initial interest and background knowledge, respectively, from the regression equations using the unstandardized regression coefficients.

analyses, but we also conducted a series of logistic regressions and obtained the same pattern of results.

We first regressed psychology major on the direct effects long-term model. This model was significant,  $F(16, 753) = 6.76$ ,  $p < .001$  ( $R^2 = .13$ ). There were significant main effects of initial interest,  $F(1, 753) = 21.42$ ,  $p < .001$  ( $\beta = .20$ ); and background knowledge,  $F(1, 753) = 12.04$ ,  $p < .01$  ( $\beta = .12$ ). In addition, the interaction of initial interest and background knowledge was significant,  $F(1, 753) = 13.79$ ,  $p < .001$  ( $\beta = .13$ ). Students who entered the class with higher levels of initial interest were more likely to major in psychology if they also had more background in psychology before they took the course ( $\hat{Y} = 0.26$ ), compared to students who did not have much background ( $\hat{Y} = 0.09$ ) and relative to students low in initial interest with high ( $\hat{Y} = 0.04$ ) or low ( $\hat{Y} = 0.05$ ) background. This interaction is graphed in Figure 4B.

**Mediated and indirect effects on psychology major.** The final long-term model was significant,  $F(21, 748) = 6.19$ ,  $p < .01$  ( $R^2 = .15$ ), and it accounted for significantly more variance than the direct effects model,  $F(5, 748) = 3.94$ ,  $p < .01$ . In this model, the main effect of hold was significant,  $F(1, 748) = 11.89$ ,  $p =$

Figure 5. Predicted values for Hold  $\times$  Final Grade interactions for courses taken (A) and for majoring in psychology (B). We computed predicted values for representative high and low groups (1 SD above and below the mean) for hold and final grade, respectively, from the regression equations using the unstandardized regression coefficients.

.001 ( $\beta = .19$ ), indicating that students who reported higher levels of hold during the introductory class were more likely to eventually major in psychology. The initial interest effect remained significant but was reduced in size ( $\beta = .12$ , from .20 in the direct effects model). A formal test of mediation revealed that this drop in beta was significant, suggesting partial mediation through hold ( $z = 3.34$ ,  $p < .01$ ). The effect of background and the interaction of initial interest with background remained significant ( $\beta$ s = .11 and .12, respectively). The interaction between hold and final grade was not significant,  $F(1, 749) = 4.49$ ,  $p < .05$  ( $\beta = .07$ ), but was in the same direction as the significant interaction reported for psychology courses taken; this is depicted in Figure 5B. Figure 6 shows the significant paths to psychology major estimated from the final long-term model.

**Direct effects on psychology grades.** For the psychology GPA analysis, our sample was limited to the 341 students who actually enrolled in additional psychology classes. The direct effects long-term model was significant,  $F(16, 324) = 2.56$ ,  $p < .01$  ( $R^2 = .11$ ), and the main effect of performance-approach goals was significant,  $F(1, 324) = 12.84$ ,  $p < .001$  ( $\beta = .21$ ), indicating that students who adopted performance-approach goals obtained higher grades in subsequent psychology classes. In addition, the main effect of courses taken was significant,  $F(1, 324) = 6.67$ ,  $p < .01$

( $\beta = .14$ ), suggesting that students who took more credits overall performed better in their psychology coursework.

**Mediated and indirect effects on psychology grades.** The final long-term model was significant,  $F(21, 319) = 12.47$ ,  $p < .001$  ( $R^2 = .45$ ), and accounted for significantly more variance than the direct effects long-term model,  $F(5, 319) = 39.36$ ,  $p < .001$ . The main effect of final grade was significant,  $F(1, 319) = 191.52$ ,  $p < .001$  ( $\beta = .62$ ). Students who received higher grades in Introductory Psychology received higher grades in their later psychology courses. The main effect of performance-approach goals was no longer significant,  $F(1, 319) = 2.38$ ,  $p = .12$  ( $\beta = .07$ ), suggesting that the direct performance-approach goal effect on psychology grades was partially mediated by grades in the introductory course. Again, this was confirmed with a formal test of mediation ( $z = 6.08$ ,  $p < .01$ ). Figure 6 shows the significant paths to psychology GPA estimated from the final long-term model.

### Reciprocal Effects of Interest and Performance

The ordering of Time 2 (catch-1) and Time 3 (catch-2 and hold) interest measures in relation to students' exams and receipt of performance feedback allowed us to examine the reciprocal relations among interest and performance. In the analyses reported previously, we found that catch-1, measured before any exams in the course, was a significant predictor of final grade, suggesting that early situational interest predicted performance. In the analyses reported in the following sections, we also tested whether catch-2 or hold predicted final grade to determine whether situational interest developed later in the semester predicted performance. Finally, to examine the reciprocal effects of performance and interest, we tested the effects of catch-1 on initial exam performance and then the effects of initial exam performance on catch-2 and hold.

**Effects of catch-2 and hold on final grade.** We tested a regression model on final grade that included the catch-1 short-term model with the addition of catch-2 and hold. In other words, we tested the incremental effects of catch-2 and hold, over catch-1, on final grade. This model,  $F(18, 839) = 7.64$ ,  $p < .001$  ( $R^2 = .14$ ), accounted for significantly more variance than the catch-1 short-term model ( $p < .001$ ). The effects of catch-2,  $F(1, 839) = 12.89$ ,  $p < .001$  ( $\beta = .17$ ); and hold,  $F(1, 839) = 6.66$ ,  $p < .01$  ( $\beta = .13$ ), were both significant, suggesting that catch-2 and hold both predicted graded performance in the class. The effect of performance-approach goals remained significant ( $\beta = .24$ ), but the effect of catch-1 was reduced from .12 to  $-.01$ . Formal tests of mediation revealed that the effect of catch-1 on final grade was mediated through both catch-2 ( $z = 3.54$ ,  $p < .01$ ) and hold ( $z = 2.39$ ,  $p < .05$ ).

Although these results suggest that catch-2 and hold promoted performance in the course, these analyses were confounded by the fact that students were aware of their performance on two exams at the point in time that we measured catch-2 and hold. It is therefore possible that performance on early exams actually influenced self-reports of catch-2 and hold. This potential confound does not apply to catch-1, however, because we measured catch-1 before any exams or feedback in the course. The first exam was taken after the assessment of catch-1 and before the assessment of catch-2 and hold, allowing us to assess the effects of first exam performance on interest, controlling for initial interest and catch-1.

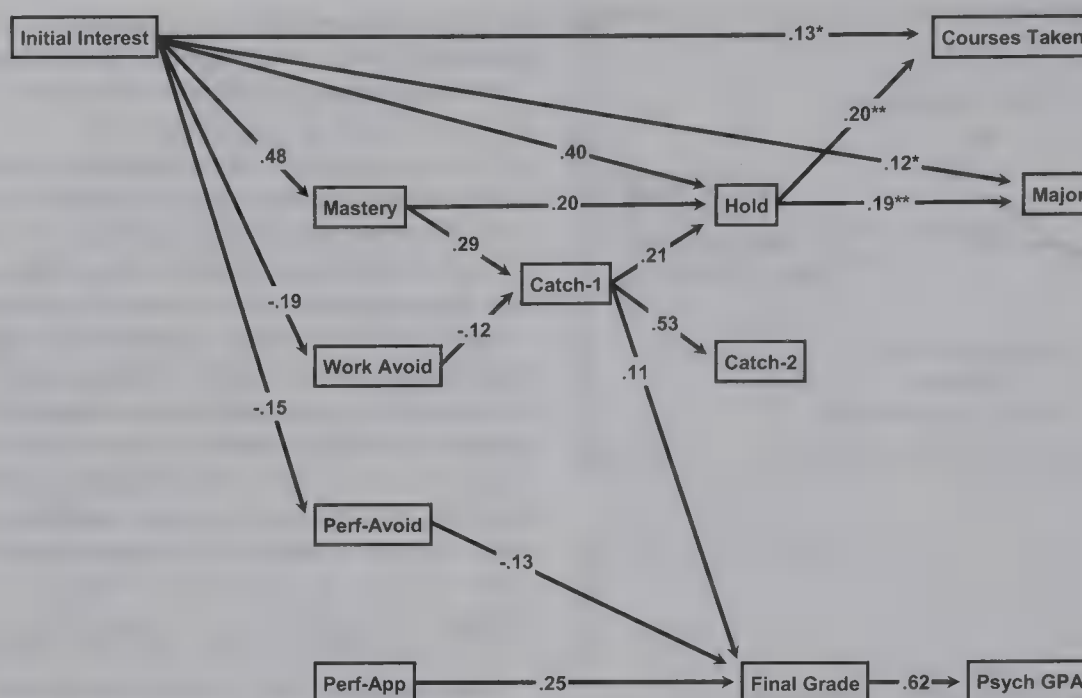

Figure 6. Predictors of long-term consequences. All paths represented are significant ( $p < .01$ ). Path coefficients are standardized regression coefficients. Paths with asterisks indicate significant interactions. Paths with a single asterisk reflect significant interaction effects between initial interest and background knowledge, whereas paths with two asterisks indicate significant interactions between hold and final grade. Separate coefficients were derived from the overall regression equation for individuals 1 *SD* above or below the mean (Aiken & West, 1991; Judd & McClelland, 1989). Specifically, the significant effect of initial interest on courses taken ( $\beta = .13$ ) and psychology major ( $\beta = .12$ ) was qualified by a significant interaction with background knowledge, such that the effect of initial interest on courses taken and psychology major was stronger for students with higher levels of background knowledge ( $\beta$ s = .24 and .33, respectively) than for students with less background knowledge ( $\beta$ s = .02 and .07, respectively). The significant effect of hold on courses taken ( $\beta = .20$ ) and major ( $\beta = .19$ ) was qualified by a significant interaction with final grade, such that the effect of hold on courses taken and psychology major was stronger for students with higher grades in Introductory Psychology ( $\beta$ s = .31 and .26, respectively) than it was for students with lower grades ( $\beta$ s = .09 and .12, respectively). For clarity of presentation, significant gender and instructor effects are not depicted, but these variables were controlled in these analyses. Mastery = mastery goals; Perf-Avoid = performance-avoidance goals; Perf-App = performance-approach goals; Work Avoid = work-avoidance goals.

We therefore examined the reciprocal effects of interest and performance by examining the predictors and correlates of performance on the first exam.

*Effects of catch-1 on early performance.* In all classes, catch-1 was measured at least 1 week prior to the first exam, allowing us to test catch-1 as an uncontaminated predictor of exam performance. When we regressed first exam score on the catch-1 short-term model, the overall model was significant,  $F(16, 841) = 4.61$ ,  $p < .001$  ( $R^2 = .08$ ). There were significant effects of performance-approach goals,  $F(1, 841) = 44.75$ ,  $p < .001$  ( $\beta = .25$ ); performance-avoidance goals,  $F(1, 841) = 8.62$ ,  $p < .01$ , ( $\beta = -.11$ ); and catch-1,  $F(1, 841) = 9.59$ ,  $p < .01$  ( $\beta = .12$ ). Students who adopted performance-approach goals, as well as students who enjoyed the course lectures, performed better on the first exam; students who adopted performance-avoidance goals performed worse.

*Effects of early performance on catch-2 and hold.* We then tested first exam performance as a predictor of catch-2 and hold, which were measured at least 2 months after the first exam. We added first exam score to the catch-1 short-term model to predict catch-2 and hold.

On catch-2, the overall model was significant,  $F(17, 840) = 38.49$ ,  $p < .001$  ( $R^2 = .44$ ), and accounted for significantly more variance than the catch-1 short-term model reported earlier ( $R^2_{\text{change}} = .02$ ,  $p < .001$ ). The effect of catch-1 was significant,  $F(1, 840) = 283.55$ ,  $p < .001$  ( $\beta = .51$ ), suggesting that students who reported higher levels of catch-1 at Time 2 also reported higher levels of catch-2 at Time 3. The effect of the first exam score was significant,  $F(1, 840) = 31.11$ ,  $p < .001$  ( $\beta = .15$ ), suggesting that students who performed well on the first exam reported higher levels of catch-2 at Time 3, controlling for the effects of catch-1.

On hold, the overall model including first exam score was significant,  $F(17, 840) = 47.59$ ,  $p < .001$  ( $R^2 = .49$ ), and accounted for significantly more variance than the catch-1 short-term model reported earlier ( $R^2_{\text{change}} = .02$ ,  $p < .001$ ). The main effects of initial interest,  $F(1, 840) = 164.17$ ,  $p < .001$  ( $\beta = .40$ ); mastery goals,  $F(1, 840) = 36.64$ ,  $p < .001$  ( $\beta = .21$ ); and catch-1,  $F(1, 840) = 41.72$ ,  $p < .001$  ( $\beta = .19$ ), were significant. In addition, the effect of first exam performance was significant,  $F(1, 840) = 31.21$ ,  $p < .001$  ( $\beta = .14$ ), suggesting that students who performed well on the first exam reported higher levels of hold at Time 3. In

sum, these results indicate that performance on an early exam can contribute to catch and hold independent of the other interest processes already documented. Considered together with the effects of catch-1 on early and later performance, these findings illustrate the dynamic relationship between interest and performance over time. Figure 7 presents a path model of the predictors of early exam performance, catch-2, and hold.

#### Ancillary Analyses on General Performance Measures

As we have done in our prior research, we also examined the predictors of general academic performance in both the short (semester GPA) and the long term (subsequent GPA). To test the direct effects of individual interest, achievement orientation, and goals, we used the 15-term basic short-term model to predict semester GPA and subsequent GPA.

**Semester GPA.** The basic short-term model was significant,  $F(15, 842) = 4.22, p < .001 (R^2 = .07)$ . Main effects of performance-approach goals,  $F(1, 842) = 36.00, p < .001 (\beta = .22)$ ; and performance-avoidance goals,  $F(1, 842) = 7.83, p < .01 (\beta = -.10)$ , showed that students who adopted performance-approach goals in their psychology class attained higher grades in all of their classes that semester, whereas students who adopted performance-avoidance goals earned lower grades.

**Subsequent GPA.** The basic short-term model was significant,  $F(15, 842) = 4.55, p < .001 (R^2 = .08)$ . There were main effects of performance-approach goals,  $F(1, 842) = 19.57, p < .001 (\beta = .16)$ ; performance-avoidance goals,  $F(1, 842) = 7.47, p < .01 (\beta = -.10)$ ; and work-avoidance goals,  $F(1, 842) = 7.59, p < .01 (\beta = -.11)$ . Students who adopted performance-approach goals in Introductory Psychology had higher grades over the course of their

academic careers, whereas students who adopted performance-avoidance or work-avoidance goals had lower grades.

#### Discussion

By situating our analyses of interest development within the context of achievement goals research, we gained insight into the role of initial interest and mastery goals in promoting the development of situational and continuing interest in an academic domain. Our results clearly indicate that interest and mastery goals are reciprocally related over time. Initial interest, measured at the outset of a college course, predicted mastery goal adoption, situational interest during the course, as well as continued interest measured several semesters later. Moreover, the effects of initial interest on continued interest were partially mediated through mastery goals, suggesting that interest can deepen over time because initial interest motivates individuals to take a task-focused approach to the material, with a desire to learn more about the topic (Renninger, 2000). This mastery goal approach then facilitates the further development and deepening of interest as students become engaged with the course material and learn more about the topic. Thus, mastery goals can be viewed as both a product and predictor of interest, or as a mediating mechanism for the continued development of interest in a topic.

We had originally contrasted these two perspectives—that interest promotes the adoption of mastery goals, and that mastery goals promote the development of interest—as separate alternatives, but it is clear from our longitudinal results that both perspectives have validity. When individuals enter a situation with interest in the topic, they may be motivated to learn more about it (i.e., adopt a mastery goal), and they may also develop more

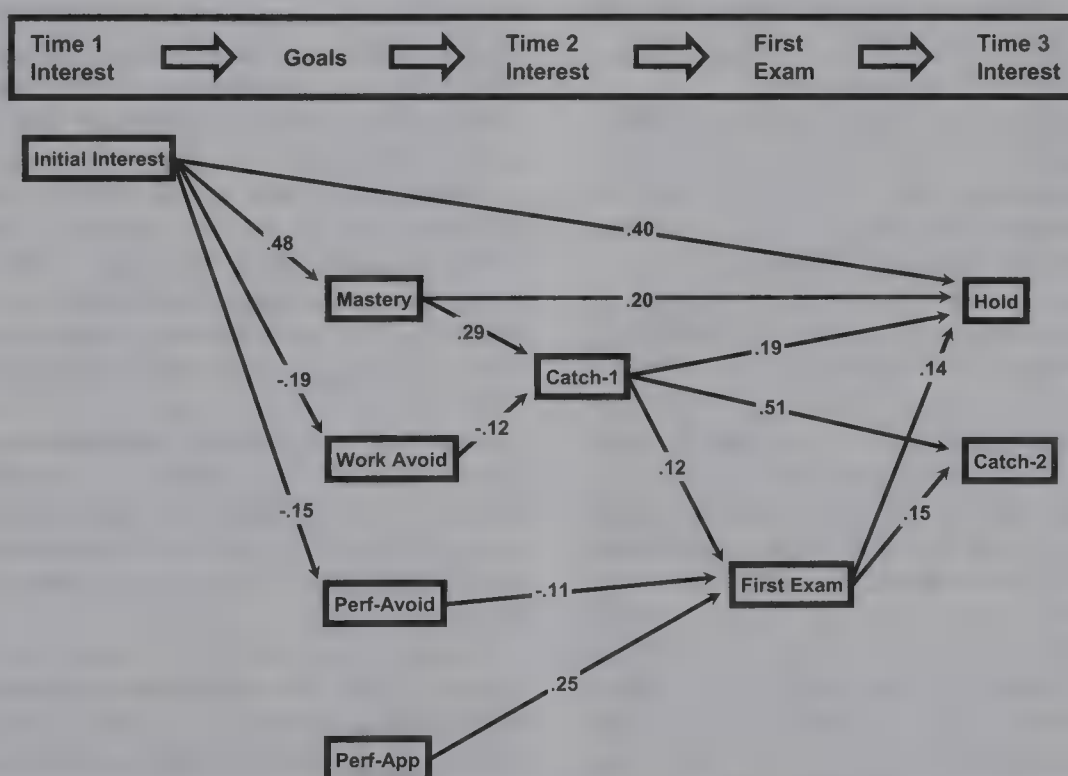

Figure 7. Reciprocal effects of interest and performance. All paths represented are significant ( $p < .01$ ). Path coefficients are standardized regression coefficients. Mastery = mastery goals; Perf-Avoid = performance-avoidance goals; Perf-App = performance-approach goals; Work Avoid = work-avoidance goals.

interest when they approach a task with a mastery goal. These two perspectives can be reconciled by distinguishing the individual interest that students bring to tasks (which can promote mastery goal adoption) from the situational interest that may develop as a result of task engagement (and mastery goal pursuit). Our findings suggest that interest must be conceptualized as an ongoing process and studied over time to elucidate the processes through which initial interest affects goal adoption and continued interest, as well as the processes through which goal adoption influences the development and deepening of interest.

Our results offer strong support for the four-phase model of interest development recently advanced by Hidi and Renninger (2006), which identifies four phases of interest development and outlines the progression from situational interest to individual interest. According to their model, the first phase of interest development is a *triggered situational interest*, in which attention, liking, or involvement is initiated by an external cue. Our lecture-specific measures of catch correspond to this early phase of interest development. If sustained over time or contexts, triggered situational interest evolves into the second phase, a *maintained situational interest*, and this phase of interest may be reflected in our measures of hold, which assessed interest in the course material. A third phase, characterized as an *emerging individual interest*, may develop out of the second phase if individuals begin to value the object or topic beyond the situation that first stimulated their interest. In this phase, individuals may be predisposed to seek out opportunities on their own to reengage with the topic of interest. This phase of interest may be reflected in our behavioral measure of continued interest, which examined students' course choices after completion of the introductory course. The third phase of interest development can then lead to the fourth, a *well-developed individual interest*, which is associated with personal meaning, value, and knowledge (Renninger, 1990). Our psychology major variable, which represents a student's extensive experience with and investment in a domain of study, seems to correspond to a well-developed individual interest.

According to Hidi and Renninger (2006), each phase is characterized by varying amounts of affect, knowledge, and value, with a greater emphasis on stimulation, affect, and liking in the early phases and a greater emphasis on meaning, value, and stored knowledge in the later phases (Renninger, 1989, 1990, 1998). The progression from catch to hold to continued interest seen in our path models maps onto the deepening of interest as described by Hidi and Renninger. In particular, the fact that the effects of mastery goals on situational interest (catch-2 and hold) were mediated by early situational interest (catch-1) suggests the mechanism through which goals can promote situational interest. Adopting a mastery goal may lead individuals to actively engage in the learning experience so that they discover the interesting and stimulating aspects of the topic (catch-1, catch-2). In the college classroom, students with a mastery goal may be more likely to notice interesting details in a text or appreciate the stimulating qualities of a lecture presentation. Over time, this heightened attention may help students gain a greater appreciation of the topic more generally or see connections to their life. In other words, triggered situational interest may develop into a maintained situational interest if students discover the value or personal relevance of the material, as suggested by the significant effect of catch-1 on hold. Our analysis is consistent with the idea that interest must be

caught before it can be held (Dewey, 1913; Hidi & Baird, 1986; Mitchell, 1993).

We also found that the effects of initial interest and mastery goals on continued interest were mediated through hold, which supports the Hidi and Renninger (2006) model by documenting how interest can deepen over time when individuals perceive value and personal relevance in a task. It is important to note that neither catch-1 nor catch-2 predicted continued interest, replicating the results of Harackiewicz et al. (2000). Although catch was important in the early stages of interest development, hold proved to be more relevant to the deepening of interest, or the transformation of situational interest into an emerging individual interest (Mitchell, 1993; Renninger, 1992). The significant interactions of hold with final grade on courses taken and major further suggest that hold was a particularly strong predictor of interest for students who received higher grades in the course. These interactions replicate results reported by Harackiewicz, Barron, Tauer, and Elliot (2002) and suggest that continued interest in a domain depends on both interest and performance. Moreover, these effects represent indirect effects of performance-approach goals on courses taken and major, because grades were predicted by performance-approach goals. Doing well in the course could contribute to the stored value of the domain (Renninger, 1992) and might therefore facilitate reentry into situations that offer the opportunity to learn more about the topic (e.g., more psychology courses). Thus, both mastery and performance-approach goals are important in predicting continued interest in an academic domain, offering further support for the multiple goals model (Harackiewicz, Barron, Pintrich, et al., 2002).

The four-phase model also affords an analysis of the effects of initial interest on subsequent interest development. We might consider students who were high in initial interest in our study to have begun the course with either an emerging or a well-developed individual interest, depending on their level of background knowledge. The fact that initial interest and background knowledge were only moderately correlated ( $r = .21$ ) suggests that there was considerable variability in the degree of background knowledge associated with high initial interest. For some students, high levels of initial interest were paired with high levels of background knowledge, indicating a well-developed interest, whereas other students reported equally high interest but lower levels of background knowledge, suggesting that they were attracted to the topic but did not have much substantive experience with it (Renninger, 2000). This suggests that individuals entered this class at many different levels along the continuum of developing interest. The interactive effects of initial interest and background knowledge on courses taken and major indicate that initial interest was a particularly strong predictor of continued interest when paired with high levels of background knowledge, supporting Renninger's (2000) assertion that strong individual interest involves knowledge of the topic.

Among students who began the class without strong interest, however, the development of interest had to begin with situational interest. Because situational interest is externally supported, these individuals could only develop interest if features of the class or aspects of the course materials triggered and then maintained their situational interest. Consequently, the students who entered the course with low initial interest but who experienced triggered situational interest may have progressed to maintained situational

interest, and possibly even to emerging individual interest. Recent experimental research supports this analysis: Instructional enhancements designed to catch interest were found to be especially advantageous for those who entered a learning situation with low initial interest (Durik & Harackiewicz, 2007). In contrast, those students who entered the class with high initial interest may have bypassed triggered situational interest and progressed from a maintained situational interest to an emerging individual interest to the extent that they found value or personal meaning in the course material. Durik and Harackiewicz also found that instructional enhancements designed to hold interest were particularly effective for individuals high in initial interest, offering further experimental support for this analysis.

We also documented the processes through which interest predicted academic performance and showed that early situational interest was a predictor of students' final grades in the course, as well as their performance on the first exam in the course (Hidi & Baird, 1986). These findings are particularly significant because our early measure of situational interest (catch-1) was collected before any exams or feedback and was therefore uncontaminated by actual or perceived performance. Although these effects were relatively small ( $\beta$ s = .11 and .12), they do suggest that motivational variables can play an important role in predicting performance. In particular, these effects are indicative of indirect mastery goal effects, because although mastery goals did not predict performance, they did predict catch-1, which then predicted performance. Although not as large as the direct performance-approach goal effect on first exam performance and final grade, these effects suggest that mastery goals may indirectly promote performance in college courses through the interest processes they engender. Moreover, the analyses with first exam performance reveal the reciprocal effects of interest and performance, notably that early interest predicted exam performance and grades, and that early exam performance predicted subsequent situational interest (both catch and hold), controlling for initial interest. These results are consistent with the idea that students perform well on tasks they find interesting and that they become more interested in activities when they have performed well on them. When students perform well on exams, their sense of competence or self-efficacy may lead them to value and enjoy that activity (Wigfield & Eccles, 1992; Zimmerman, 1985). Again, two alternative perspectives (that interest influences performance, and that performance influences interest) can be resolved by studying these processes over time to elucidate the reciprocal relations among these important variables.

The effects of early situational interest on performance and subsequent situational interest (hold) indicate the importance of externally supported interest and suggest that educators may be able to influence performance and continued interest through situational interest. If triggered situational interest was the critical factor for engaging students who were initially uninterested in the material, then it is important to identify what types of classroom environments best promote triggered situational interest. It is not known whether instructional technology, the organization of the material, or the instructor's style triggered situational interest in this study, but understanding learners' responses to such situational variables will be critical for designing instructional contexts that maximize student interest and performance. Experimental research has begun to examine the instructional factors that affect

situational interest, such as whether the task is visually appealing and whether the utility value of the material is emphasized (Durik & Harackiewicz, 2007), but more work is needed to better understand how situational factors can be used in classroom environments to promote optimal motivation.

Moreover, future research should examine how situational and individual interests combine across longer spans of time and during different periods of personal development. Parents and peers may affect situational interest in activities over time, influencing the extent to which individuals have contact with various domains, adopt achievement goals, and identify them as meaningful and interesting. The influence of parents might be especially prominent for young children, whereas the influence of peers might be more prominent during adolescence. Although the present study begins to elucidate how interest and goals unfold over time within an introductory college course, it will be important to extend these analyses beyond the college classroom in future research.

## Appendix

## Scale Items and Reliabilities

## Time 1 Items

Initial interest ( $\alpha = .90$ )

I've always been fascinated by psychology.

I chose to take Introductory Psychology because I'm really interested in the topic.

I'm really excited about taking this class.

I'm really looking forward to learning more about psychology.

I think the field of psychology is an important discipline.

I think what we will study in Introductory Psychology will be important for me to know.

I think what we will study in Introductory Psychology will be worthwhile to know.

Background knowledge ( $\alpha = .90$ )

This class is my first exposure to the field of psychology. (reversed)

I already have some background in psychology (e.g., I studied psychology in another class or did reading on my own).

I have very little experience with psychology. (reversed)

Workmastery (Helmreich & Spence, 1978; Spence & Helmreich, 1983;  $\alpha = .80$ )

I like to work hard.

There is satisfaction in a job well done.

I more often attempt tasks that I'm not sure I can do than tasks I believe I can do.

I would rather do something at which I feel confident and relaxed than something which is challenging and difficult.

I find satisfaction in working as hard as I can.

I would rather learn easy and fun games than difficult thought games.

Once I undertake a task I persist.

I find satisfaction in exceeding my previous performance even if I don't outperform others.

I like to be busy all the time.

Part of my enjoyment in doing things is improving my past performance.

When a group I belong to plans an activity, I would rather direct it myself than just help out and have someone else organize it.

I prefer to work in situations that require a high level of skill.

It is important to me to do my work as well as I can even if it isn't popular with my peers.

If I am not good at something, I would rather keep struggling to master it than move onto something I may be good at.

Competitiveness (Helmreich & Spence, 1978; Spence & Helmreich, 1983;  $\alpha = .75$ )

I feel that winning is important in both work and games.

I try harder when I'm in competition with other people.

It annoys me when other people perform better than I do.

I enjoy working in situations involving competition.

It is important to me to perform better than others on a task.

## Time 2 Items

Mastery goal orientation ( $\alpha = .87$ )

The most important thing for me in this course is to understand the content as thoroughly as possible.

Mastering the material in Introductory Psychology is important to me.

I want to learn as much as possible in this class.

I like it best when something I learn in this course makes me want to find out more.

In a class like this, I prefer course material that really challenges me so I can learn new things.

My goal in this class is to learn as much as I can about this topic.

In a class like this, I prefer course material that arouses my curiosity even if it is difficult to learn.

Performance-approach goal orientation ( $\alpha = .87$ )

It is important for me to do well compared to others in this class.

I don't care about how I do compared to the other students in this class. (reversed)

I want to do better than other students in this class.

My goal in this class is to get a better grade than most of the other students.

Performance-avoidance goal orientation ( $\alpha = .78$ )

I just want to avoid getting a low grade in this class.

I just want to avoid doing poorly in this class.

Work avoidance goal orientation ( $\alpha = .90$ )

I want to get through this course by doing the least amount of work possible.

I want to do as little work as possible in this class.

I don't want to work hard in this class. (reversed)

Catch-1 ( $\alpha = .85$ )

I look forward to coming to this class.

Lectures in this class really seem to drag on forever. (reversed)

I think the lectures are interesting.

The lectures in this class are entertaining.

Time 3 Items

Catch-2 ( $\alpha = .91$ )

I like my instructor.

The lectures in this class really seem to drag on forever. (reversed)

I don't like the lectures very much. (reversed)

I enjoy coming to lecture.

The lectures in this class aren't very interesting. (reversed)

Hold ( $\alpha = .95$ )

To be honest, I just don't find psychology interesting. (reversed)

I think the field of psychology is very interesting.

Psychology fascinates me.

I'm excited about psychology.

I think what we are learning in this course is important.

I think what we are studying in Introductory Psychology is useful for me to know.

I find the content of this course personally meaningful.

I see how I can apply what we are learning in Introductory Psychology to real life.

I think the field of psychology is an important discipline.

# A Response to Recent Reanalyses of the National Reading Panel Report: Effects of Systematic Phonics Instruction Are Practically Significant

Karla K. Stuebing, Amy E. Barth, Paul T. Cirino, David J. Francis, and Jack M. Fletcher  
University of Houston

The authors examine the reassessments of the National Reading Panel (NRP) report (National Institute of Child Health and Human Development, 2000) by G. Camilli, S. Vargas, and M. Yurecko (2003); G. Camilli, P. M. Wolfe, and M. L. Smith (2006); and D. D. Hammill and H. L. Swanson (2006) that disagreed with the NRP on the magnitude of the effect of systematic phonics instruction. Using the coding of the NRP studies by Camilli et al. (2003, 2006), multilevel regression analyses show that their findings do not contradict the NRP findings of effect sizes in the small to moderate range favoring systematic phonics. Extending Camilli et al. (2003, 2006), the largest effects are associated with reading instruction enhanced with components that increase comprehensiveness and intensity. In contrast to Hammill and Swanson, binomial effect size displays show that effect sizes of the magnitude found for systematic phonics by the NRP are meaningful and could result in significant improvement for many students depending on the base rate of struggling readers and the size of the effect. Camilli et al. (2003, 2006) and Hammill and Swanson do not contradict the NRP report, concurring in supporting comprehensive approaches to reading instruction.

**Keywords:** reading instruction, phonics, National Reading Panel, meta-analysis

The report of the National Reading Panel (NRP; National Institute of Child Health and Human Development [NICHD], 2000), a congressionally mandated effort to synthesize research on effective instructional methods for teaching children to read, continues to generate controversy. The NRP report was completed by a committee under the direction of the NICHD in collaboration with the U.S. Department of Education. Despite the use of an empirical approach to the synthesis of research results (meta-analysis), with two peer-reviewed articles representing the syntheses of phonics and phonological awareness instruction (Ehri, Nunes, Stahl, & Willows, 2001; Ehri, Nunes, Willows, et al., 2001), the report, and especially the part involving phonics, has been highly scrutinized since it was released in 2000. Several reviewers have disagreed with NRP conclusions supporting the efficacy of systematic phonics instruction over other approaches to teaching phonics (Allington, 2002; Garan, 2001; see responses by Cooper, 2005; Shanahan, 2004).

Recently, two critiques of the phonics meta-analysis of the NRP report were published in a special issue of the *Elementary School*

*Journal* (Camilli, Wolfe, & Smith, 2006; Hammill & Swanson, 2006). Camilli et al. (2006) provided a second reanalysis of the studies coded by the NRP. In their first reanalysis of the NRP report, Camilli, Vargas, and Yurecko (2003) concluded that the actual effect size from studies involving systematic phonics instruction in the NRP report was  $d = 0.24$  when studies were weighted equally (i.e., without correction for sample size) and  $d = 0.188$  when studies were weighted by a combination of equal representation and sample size. These estimates were much lower than the  $d = 0.41$  reported by the NRP for end-of-training outcomes. In Camilli et al. (2006), more extensive coding of study characteristics was provided, along with appropriate multilevel analysis techniques, leading to  $d = 0.123$  for systematic phonics, which was characterized as not significant and a “weak intervention” (p. 31).

In a similar vein, Hammill and Swanson (2006) converted the estimates of effect size in the NRP report to metrics ( $R^2$ ) that represent the amount of explained variance. Although acknowledging that “94% of the  $d$ ’s supported the superiority of phonics instruction over other approaches,” they went on to observe that “Cohen would describe 65% of these significant  $d$ ’s as small” (p. 19). Converting the  $d$ s to  $r$ s yielded an overall  $r = .21$ , or  $R^2$  of .04, “suggesting that 96% of the variance in reading achievement can be attributed to factors other than the systematic phonics instruction” (p. 18). The authors concluded that “for all practical purposes, the advantages of phonics versus nonphonics instruction have not been demonstrated” (p. 25).

## Theoretical and Pedagogical Issues

Underlying the controversy over phonics and its role in reading instruction is a set of theoretical issues about learning to read that relate directly to how the alphabetic principle is taught (American

Francis, Department of Psychology; Texas Institute for Measurement, Evaluation and Statistics; and the Texas Center for Learning Disabilities, University of Houston; Jack M. Fletcher, Department of Psychology and the Texas Center for Learning Disabilities, University of Houston.

Grant P50 HD052117 from the National Institute of Child Health and Human Development to the Texas Center for Learning Disabilities supported this article. David J. Francis was a methodological consultant to the National Reading Panel (NRP). No other authors were involved with the NRP and its report.

Correspondence concerning this article should be addressed to Jack M. Fletcher, Department of Psychology, University of Houston TMC Annex, 2151 West Holcombe Boulevard, Suite 222, Houston, TX 77204-5355. E-mail: jackfletcher@uh.edu

Federation of Teachers, 1999; Pressley, 2005; Stanovich, 2000). Unlike in previous periods, the current discussion is rarely about whether any instruction involving the alphabetic principle should be provided, but (a) how systematically instruction should be conducted to ensure that all students have adequate knowledge of the alphabetic principle, and (b) the extent to which students are better served by opportunities to make inferences and develop their own understanding of the role of the alphabetic principle versus opportunities in which the alphabetic principle is directly taught by the teacher (Allington, 2002; Rayner, Foorman, Perfetti, Pesetsky, & Seidenberg, 2001). These differences are often represented as a dichotomy comparing a scripted curriculum with a defined scope and sequence versus a curriculum that encourages discovery of the alphabetic principle through immersion in literature.

Underlying this dichotomy is a continuum that reflects the extent to which the student is expected to infer and construct new knowledge versus learn through the direct, explicit sharing of the new knowledge by the teacher. The NRP coded studies involving phonics to capture this continuum, comparing studies that included "systematic phonics," characterized by "a planned, sequential introduction of a set of phonics elements along with teaching and practice of these elements" (NICHD, 2000, p. 2-89), with those that included "unsystematic phonics," in which there was evidence of some phonics instruction but not in a planned, sequential fashion, and "no phonics," in which there was no evidence of any attempt to teach phonics except incidentally. In the latter programs, the instruction might focus on the teaching of whole words or might incidentally address the development of phonics skills within reading, writing, listening, and speaking activities as the need arises (NICHD, 2000). The overall effect size reported by the NRP favored systematic phonics over other forms of phonics instruction.

### Estimation of the NRP Effect Sizes: Hypothesis 1

The studies by Camilli et al. (2003, 2006) and Hammill and Swanson (2006) are empirical reassessments of the NRP results. Both essentially minimize the findings of the NRP on the efficacy of reading instruction that includes systematic phonics and therefore downplay instructional theory and pedagogy that focuses on planned, systematic instruction in the alphabetic principle for all students.

If the level of systematicity of phonics instruction is primarily responsible for the treatment effect, a dosage hypothesis may be in effect. The largest effect sizes should be associated with the strongest dose – or systematic phonics compared to the no phonics control. Smaller effect sizes should be associated with comparisons of systematic phonics with unsystematic phonics and also with comparisons of unsystematic phonics with no phonics. This simple main effects hypothesis was the initial comparison made in the NRP report and as an average, does not take into account the possibility that the instruction might interact with child characteristics; some children who are weaker in alphabetic skills may need more explicit phonics instruction (e.g., Connor, Morrison, Fishman, Schatschneider, & Underwood, 2007; Foorman, Francis, Fletcher, Schatschneider, & Mehta, 1998), whereas the degree of systematic phonics instruction may be less important for other children with better developed letter-sound knowledge. This main effect hypothesis also ignores the fact that type of instruction may

interact with school and teacher characteristics (e.g., teaching competence, time allocation; Connor et al., 2007; Foorman et al., 2006). Nonetheless, the dosage hypothesis is a useful heuristic for understanding the NRP report and its subsequent evaluations.

In calculating effect sizes, the NRP held the treatment constant, comparing the systematic phonics group from each study to any available comparison group. Some of the effect sizes represent contrasts between systematic phonics and some phonics, whereas other effect sizes represent contrasts between systematic phonics and true no phonics control groups. The  $d$  of 0.41 is the average of two groups of effects: (a) systematic phonics contrasted with some phonics, and (c) systematic phonics contrasted with no phonics. The NRP report did break down effects using type of comparison group as a moderator. The largest effects represented comparisons of systematic phonics to whole-word instruction (average  $d = 0.51$ ), and the smallest average effects represented comparisons wherein the control group had "whole language" instruction ( $d = 0.31$ ).

Camilli et al. (2003) did not accept the NRP premise that the average of different levels of phonics intervention was a meaningful comparison, focusing on study characteristics that might moderate the NRP effect size estimates. They identified two effect sizes that they felt had been miscalculated and disagreed with the inclusion of one study (Vickery, Reynolds, & Cochran, 1987) that they felt did not meet inclusion criteria and was noteworthy because it contributed eight effect sizes to the NRP database. They also identified studies in the NRP database that they felt should have been included by the NRP. Based on these modifications, Camilli et al. (2003) then recoded all of the studies from the set used by the NRP to make a different set of comparisons. They held constant the control group—always using the no phonics control and contrasting it to what they coded as "some phonics" treatments and "systematic phonics" treatments. Additionally, they coded comparisons across all groups in each study. For example, if there was a group that received a whole-word treatment, it would be compared to the no treatment (or standard practice) control group. As a result, Camilli et al. (2003) produced a much larger number of effects from these studies by coding for comparisons among all group means, which included some comparisons for which there was no phonics in either the treatment or control group. They also generated different estimates of effect size because the comparisons were adjusted to account for the presence of study moderators.

A potential limitation of these estimates is that the literature search was not designed to address the comparisons made in Camilli et al. (2003). Studies that compared no phonics and some phonics would not necessarily have been identified by the NRP search strategy. Additionally, the NRP search strategy was not designed to locate studies that compared no phonics or some phonics to a standard treatment control with systematic language activities. Finally, the NRP estimated the effect of systematic phonics instruction by taking weighted averages of the effects, both overall and within specific hypothesized moderator groups. Camilli et al. (2003) estimated the effects of systematic phonics instruction by predicting the effects via a regression equation that included recoding of the NRP studies for the amount and degree of systematicity of phonics in the treatment; whether there were "systematic language activities" in the treatment group and/or control group; and the intensity of the treatment delivery, repre-

sented as tutoring versus small-group-/classroom-level delivery. The effect size compared to the NRP overall  $d = 0.41$  was a regression weight that represented the difference between systematic phonics and some phonics controlling for the other intervention characteristics that were in the model.

Altogether, the NRP report and Camilli et al. (2003) ask different questions. The NRP question is analogous to asking about the value of receiving the intervention versus not receiving the intervention. The Camilli et al. (2003) report is analogous to asking what is the value of receiving a strong form of the intervention compared to receiving weaker forms of the intervention and relative to factors that moderate the outcomes. From our view, both questions are reasonable for intervention studies; it is worthwhile to know the average effect of supplying the intervention (i.e., the NRP report approach), but it is also worthwhile to know the incremental value of adding the intervention over and above the value of other characteristics of students, classrooms, and teachers that might affect outcomes (i.e., the Camilli et al. [2003] approach).

One would expect the estimates of effect size from Camilli et al. (2003) and the NRP to differ because the questions were different and (a) the results were based on a slightly different set of studies; (b) a different approach was used to code effects; and (c) the overall NRP effect was an unadjusted effect, whereas the Camilli et al. (2003, 2006) effects were adjusted for other study characteristics. Our first hypothesis is that when the same question is asked of the Camilli et al. (2003) data (i.e., the parameters estimated are the same), the magnitude of the effects of systematic phonics in Camilli et al. (2003, 2006) will be comparable to that of the NRP report.

### Comprehensive Approaches to Reading Instruction: Hypothesis 2

In addition to the NRP report, other consensus reports, including the National Research Council report (Snow, Burns, & Griffin, 1998) and the report of the RAND Reading Study Group (2002), have argued for comprehensive approaches to reading instruction that include literacy activities that extend beyond alphabets. This question was tested by Camilli et al. (2003) and further addressed by Camilli et al. (2006), who employed a multilevel analysis to account for the dependence of multiple effect sizes from the same studies. As discussed previously, Camilli et al. (2003) also coded for other components of instruction that were wrapped in with phonics instruction in the treatment, including systematic language activities and intensity. Note that the coding of language activities in Camilli et al. (2006) used "systematic" in a different manner from the NRP, referring primarily to the presence of literacy activities believed to facilitate fluency and comprehension and not to the degree of explicitness. These activities represented the extent to which teachers incorporated components of reading that extend beyond alphabets, emphasizing a print-rich environment, independent reading, purposeful writing, the use of invented spelling, and the use of literature to teach higher order skills. Tutoring is not really another component of reading but is a means of delivering instruction in a manner that allows for more practice at a smaller teacher-student ratio, thus increasing the intensity of instruction.

In the final models presented by Camilli et al. (2003, 2006), the individual components of the instruction all added significantly to the prediction of the effect size. Not emphasized was the implication that the overall effect size for a more comprehensive approach could be quite large. To address this question we repeated the multilevel regression analysis with modifications to the data set that permitted a more straightforward presentation of the value of adding additional activities to the reading program. Our second hypothesis is that in this stricter comparison, which allows separate empirically derived estimates of the effect of additional literacy activities on top of both some phonics and systematic phonics, effect sizes will be larger when additional literacy activities and tutoring are added to the effects of systematic phonics instruction.

### Effect Sizes in Context: Hypothesis 3

Even the critics of the NRP report concede that different studies show small effects significantly favoring systematic phonics; they disagree that these effect sizes are practically important, which is the point of departure for Hammill and Swanson (2006). Evaluating the practical utility of treatment effects is an important issue, which Hammill and Swanson addressed by translating the  $d$ s into their associated  $r$ s and  $R^2$ s and then classifying these values using an idiosyncratic variation on Cohen's suggested rules of thumb for choosing an effect size for a priori estimation of statistical power. We do not question the general heuristic labeling of effect sizes as *small* ( $r = .1$  and  $d = 0.2$ ), *medium* ( $r = .3$  and  $d = 0.5$ ), or *large* ( $r = .5$  and  $d = 0.8$ ) (Cohen, 1988) but question the use of these heuristics by Hammill and Swanson because they were never intended to be strict rules or thresholds for judging the utility of intervention effect sizes.

Cohen proposed that when conducting a power analysis in the planning stages of research, the researcher should first look to prior research in the same field to get an idea of the size of an effect that might be expected, which permits an estimate of the sample size that will be required to minimize the risks of a Type II error (in this context, identifying a treatment as ineffective when in fact it was effective). If the researcher is not able to obtain a numeric value to use in the power analysis calculations, Cohen (1988) proposed the use of the now familiar effect size heuristics but warned against their misuse and abuse. He stated:

The author proposes *as a convention*, [effect size] values to serve as operational definitions of the qualitative adjectives "small", "medium", and "large." This is an operation fraught with many dangers: The definitions are arbitrary, such qualitative concepts as "large" are sometimes understood as absolute, sometimes as relative; and thus, they run the risk of being misunderstood. (p. 12)

Cohen (1988) also insisted that the importance of an effect could not be discerned from its size independently of its context, indicating that "the *meaning* of any given [effect size] is, in the final analysis, a function of the context in which it is embedded" (p. 535). Small effect sizes for important outcomes may have significant implications in a practical context (Trusty, Thompson, & Petrocelli, 2004). Furthermore, small effects in ongoing processes, such as the development of key skills underlying reading, may accrue over time to become moderate to large effects (Prentice & Miller, 1992). Conversely, large effect sizes may be trivial within practical contexts because the spuriously large effect was the result

of method variance and response biases (Thorndike, 1997) and from specification error and outliers (Pedhazur, 1982). As Cohen (p. 535) stated,

"only 50% of the variance" may be as valid a formulation in one context as "only 1% of the variance" is in another, and conversely, "as much as 1% of the variance" is, in principle, no less valid a formulation than "as much as 50% of the variance."

Thus, one-size-fits-all rules of thumb may not help to interpret an effect size in the absence of the context in which it is to be operationalized (Vacha-Haase & Thompson, 2004).

Considering the caveats provided by Cohen (1988), the labeling of effect sizes can serve as an aid to communication, in the sense that a large effect from a high-quality study is nearly always "better" than a small or medium effect. Although difficulty in making decisions about the practical impact of a given effect size is less likely in the case of an effect size with a large value (e.g., in the range of about  $d = 0.80$ ), even here one might envision a hypothetical situation in which, given a significant cost to obtain the result, an effect size of this absolute magnitude might carry little practical meaning. For example, individual tutoring may have a larger effect size than classroom-based instruction, but providing 1:1 instruction to every single student in public schools carries an unrealistic cost, not to mention the logistical difficulties of training sufficient numbers of teachers, rebuilding schools to support tutoring, and so on. However, as effect sizes become progressively lower in absolute value, an evaluation of contextual factors is more likely to be required, which is more complicated than simply comparing an effect size to some benchmark. A consideration of costs and benefits may be required. Although labels can be used with effect sizes, the utility of the effect under consideration is not synonymous with its label. For example, although the translation of *small* into  $d = 0.2$  could be useful when planning research, the translation of *small* into *of little utility and of little practical importance* is a much more tenuous proposition and is likely to be biased without a consideration of context.

A clear example of such an effect is the well-known 5-year randomized study that led to the recommendation to utilize aspirin in the prevention of heart attack (Steering Committee of the Physicians' Health Study Research Group, 1989). The absolute value of the effect size from this study was  $d = 0.07$ , which is *negligible* under heuristic guidelines of standard deviation units and certainly unimpressive in terms of correlation ( $r = .034$ ) or in terms of proportion of variance ( $R^2 = .001$ ). However, given the low base rate of heart attack (1.33% in that study), the effect size of  $d = 0.07$  means that nearly twice as many individuals in the placebo group suffered a heart attack relative to individuals in the aspirin condition. In the context of the low base rate and high costs of heart attacks and the generally low cost of aspirin, this effect size moves from unimpressive to powerful.

The average effect sizes of different educational interventions are larger than that in the aspirin example. Lipsey and Wilson (1993) reported that the average educational intervention had an effect size of  $d = 0.34$ , or  $r = .168$ , which is  $R^2$  of .028. In another large meta-analysis, Swanson, Hoskyn, and Lee (1999) reported an average weighted effect size of  $d = 0.56$  for the effects of educational interventions in people identified with learning disabilities across a wide variety of outcome measures. The latter effect size is larger than the average effect for phonics in the NRP report,

which in turn is larger than that of Lipsey and Wilson. Potential explanations for the variability of these results include differences in the interventions; the populations, which differed by age and subgroup; as well as methodological quality; research design; and so on. The Lipsey and Wilson meta-analysis involved a variety of educational interventions in kindergarten through Grade 12 and college. In contrast, the effect size reported by Swanson et al. was for individuals with learning disabilities in kindergarten through Grade 12. The NRP effect size of  $d = 0.41$  was for phonics interventions in kindergarten through Grade 6 over all subgroups. However, note that for poor readers, the NRP reported an effect size of  $d = 0.98$  for decoding regular words and  $d = 0.67$  for decoding pseudowords in kindergarten through Grade 2 and  $d = 0.49$  for decoding regular words and  $d = 0.52$  for decoding pseudowords in Grades 2 through 6. These latter values are especially comparable to the  $d = 0.57$  reported by Swanson et al. for the effect of intervention in groups with learning disabilities on word recognition. Obviously none of these meta-analyses were exact replications of one another. The amount of variation in these estimates is consistent with the possible effects of the moderators mentioned previously as well as expected sampling error. The next step, however, is not to compare the obtained effect to a one-size-fits-all rule of thumb or convention, but to use these estimated effects to determine the utility of implementing various types of interventions by taking into account contextual factors.

In the case of interventions designed to improve reading performance, identifying factors such as the base rate of struggling readers and the cost of interventions as well as the cost of not providing an intervention (e.g., the cost that might be represented by dropping out of high school) can assist in contextualizing the effect sizes found by either the NRP study or the Camilli et al. (2003, 2006) analyses. To address this question, we used the effect size estimates from the NRP report and different estimates of the incidence of reading difficulties and a variant of a binomial effect size display (Rosenthal & Rubin, 1982) to evaluate the importance of context in interpreting effect size data. Consistent with Cohen (1988), our third hypothesis is that interventions with effect sizes as small as those identified by Hammill and Swanson (2006) for phonics instruction could significantly reduce the number of children with reading problems depending on the base rate used to estimate the incidence of reading difficulties and the effect size associated with different interventions.

## Hypothesis 1

### Method

**Database.** To address the first hypothesis concerning the impact of study parameters on the discrepancies in the NRP report and in Camilli et al. (2003), we relied on the corpus of studies identified by the NRP and recoded by Camilli et al. (2003, 2006). These studies and the database of effect sizes and codes were accessed from the online journal *Education Policy Archives Analysis* Web site in which Camilli et al. (2003) originally appeared (<http://epaa.asu.edu/epaa/v11n15>). Although several questions were asked in the section of the NRP report addressing phonics, the first question was the target of both Camilli et al. (2006) and Hammill and Swanson (2006): "Does systematic phonics instruction help children learn to read more effectively than nonsystem-

atic phonics instruction or instruction teaching no phonics?" (NICHD, 2000, p. 2-92). The primary criterion for including studies into this meta-analysis was stated in the NRP methodology: "Studies had to provide data testing the hypothesis that systematic phonics instruction improves reading performance more than instruction providing unsystematic phonics or no phonics instruction." (NICHD, 2000, p. 2-90). This criterion requires that a study include a comparison of systematic phonics instruction versus any other control condition, which is what the  $d = 0.41$  in the NRP report represents. Some of these control conditions will have no phonics and others will have unsystematic phonics. With this strategy and other criteria, the NRP screened 75 studies representing randomized or quasi-experimental designs with treatment and control groups, with 38 represented in the final database. Camilli et al. (2003) included substantially the same set of studies included in the NRP meta-analysis, removing one study and adding three from the corpus of studies identified by the NRP (no new search was conducted).

**Predictors.** The dependent variable in Camilli et al. (2003) was the effect size, and the independent variables were coded vectors that represented many other characteristics of the intervention given in each study. After a stepwise regression procedure, their final model included as predictors the amount and degree of systematicity of phonics in the treatment; the presence of systematic language activities in the treatment group and/or control group; and the intensity of the treatment delivery, represented as tutoring versus small-group-/ classroom-level delivery.

**Procedures.** We reformulated the results from the two studies within the same framework. To further understanding of the dosage hypothesis and what it means for comparing effect size estimates from the NRP report and Camilli et al. (2003), consider Figure 1. The horizontal axis represents performance on some reading outcome measure. We hypothesized that the average performance associated with no phonics would be at the far left (lowest performance), the average performance for systematic phonics would be on the far right (highest performance), and the average performance associated with unsystematic or some phonics would be in between these two extremes. The line segments connecting the three groups represent the distance in effect size units between each pair. Line segment *a* represents the average effect between systematic phonics and a no phonics control group,

line segment *b* represents the average effect between some phonics and a no phonics control group, and line segment *c* represents the difference between systematic phonics and some phonics groups. We can use this generic framework to highlight the different elements that are being considered in the NRP report and in the Camilli et al. (2003, 2006) reports and to demonstrate why we would not expect the numbers they report to be the same, even in the context of the same studies.

The NRP asked about the effects of systematic phonics instruction. Therefore, they coded some studies that compared systematic phonics to a no phonics control (represented by line segment *a*) and other studies that compared systematic phonics to a some phonics control (line segment *c*). They then averaged the set of *a* and *c* effects to get  $d = 0.41$ . Note that the size of this average depends on the average size of *a*, the average size of *c*, and the number of studies providing estimates of *a* and *c* found in the literature. If, consistent with our model, *as* are systematically larger than *cs* and there are more of them, the overall average will be larger than if the proportion of *as* and *cs* had been reversed. The NRP also included a test of the homogeneity of the distribution of effects and found that they were not homogenous. When effects are not homogenous, presenting the overall effect is only Step 1, followed by presentation of the effects within moderator groups. As a result, the NRP presented the average effects within many potential moderator groups, including one breakdown that showed that the effect size differed depending on the type of control group.

Camilli et al. (2003) recoded all of the effects to arrive at a different set of comparisons. They made all comparisons against a no phonics control, thus estimating the quantities *a* and *b* in Figure 1. Note that they also coded estimates of the difference between groups where neither of the groups received any phonics instruction. An example would be a comparison between a treatment group receiving whole-word instruction and a control group receiving standard instruction. This contrast cannot be represented in Figure 1, which represents the continuum of the phonics treatment effects. In studies that included a systematic phonics group, a some phonics group, and a no phonics control group, Camilli et al. (2003) coded both difference *a* and difference *b*, thus obtaining more comparisons from the same set of studies than the NRP analysis. They then analyzed the coded effects in a regression

Figure 1. Model for comparisons of effect sizes from the National Reading Panel report and Camilli et al. (2003, 2006).

analysis to estimate and test the  $c$  difference (i.e., the difference between systematic phonics and some phonics).

The conceptual difference between the two approaches is that the NRP estimated the average of a mixed set of effects ( $a$  and  $c$ ) and then tested the distribution of these effects to determine if they were homogenous. Camilli et al. (2003) estimated  $c$ , the average difference between the estimates of effects  $a$  and  $b$ , and tested whether there was a significant difference when the set of effects was divided along the some phonics–systematic phonics dimension. The overall average, or the NRP estimate, is almost certainly going to be larger than  $c$  regardless of the mix of  $a$ s and  $c$ s, provided there is at least one  $a$  effect in the group of estimates. We used the model in Figure 1 as a framework for comparing estimates of effect size in Camilli et al. (2003) and the NRP report.

## Results

Camilli et al. (2003) provided several different estimates for  $c$ . The first was presented in the context of their Table 3, in which the average univariate effect for comparisons of systematic phonics with no phonics controls was  $d = 0.514$  and the average comparison of some phonics with no phonics controls was  $d = 0.243$ . To put this into the context of Figure 1, the former was their estimate of the average  $a$  effect; the latter was their estimate of the  $b$  effect. We can calculate the difference between the two to arrive at an estimate of  $c = .27$ . Camilli et al. (2003) pointed out that their estimate of the effect of systematic phonics was about 30% smaller than the effect reported by the NRP. They failed to underscore the fact that .27 is only an estimate of the average  $c$  effect and not, like the NRP average, an estimate of the average of the mixed  $a$  and  $c$  effects, which Figure 1 shows must be larger. We do not know how many  $a$  and  $c$  effects were coded by the NRP because we based our reanalysis on the Camilli et al. (2003) data set, which did not contain this information. However, if we make the simplifying assumption that there are equal numbers of  $a$  and  $c$  effects and use these estimates of  $a$  and  $c$  (.514 and .27), our estimate of the average effect is  $(.514 + .27) / 2$  or  $d = 0.39$ , which is remarkably close to the value of  $d = 0.41$  obtained in the NRP analysis. Thus, when we estimate the same parameter, the results of the two coding rubrics converge despite slight differences in the corpus of studies.

Other estimates of the  $c$  effect can be obtained from Camilli et al. (2003). Specifically, their Tables 6 and 7 display the parameter estimates from their final regression equations after stepwise analysis, in which the effect sizes are predicted from a number of study characteristics, including the amount of systematic language instruction in the treatment, the amount of systematic language instruction in the control group, and whether tutors were used to deliver instruction versus small groups or whole classrooms. These two sets of results differed in the weights that were applied in the analysis. The results from their Table 6 used weights ( $WGT$ ) that gave equal representation to each study, where  $k$  represents the number of records contributed to the database by each study:  $WGT1 = 1 / k$ .

The results from their Table 7 used compromise weights ( $WGT3$ ), or weights that resulted from multiplying equal representation weights with optimal weights (Hedges & Olkin, 1985, p. 110), which are a function of the sample size and effect size from

each study. See Equations 1 and 2 and Camilli et al.'s (2003) Table 4 for a description of these weights:

$$WGT3 = WGT1 \times WGT2 \quad (1)$$

where

$$WGT2 = \left( \frac{n_{TOT}}{n_T n_C} + \frac{d^2}{2(n_{TOT} - 2)} \right)^{-1} \quad (2)$$

For both analyses, the regression weight associated with  $TP2$  is the parameter estimate of interest. This parameter represents the difference between (a) the effects that compare systematic phonics with a no phonics control and (b) those that compare some phonics with a no phonics control, which, in the context of Figure 1, is an estimate of  $c$ . However, in these models, the effect size estimate has been adjusted for the presence of other study characteristics; the systematic phonics effect has been corrected for the presence of systematic language activities in the same treatment or for treatment delivery through tutoring. The effect is to make the average of the  $a$  effects and the  $b$  effects closer to each other. When equal representation weighting is used (i.e.,  $WGT1$ ), the best estimate of  $c$  is .241; when compromise weighting is used (i.e.,  $WGT3$ ), the best estimate of  $c$  is .188. These estimates are lower than the NRP estimate but should not be directly compared to it because the NRP estimate is an average of the  $a$  and  $c$  effects.

In the same vein, Camilli et al. (2006) presented a third estimate of  $c$  in the context of a multilevel model that permitted control for the dependencies among effects from the same study. The parameter estimates from this model indicated that the effect of moving from some phonics to systematic phonics was  $d = 0.123$  when other study characteristics and the dependency of effects within studies were controlled. Again, this is an estimate of the  $c$  effect adjusted for study moderators and cannot (and should not) be directly compared to the NRP unadjusted average of a mixed set of  $a$  and  $c$  effects of  $d = 0.41$ .

Another approach to estimating the effect size obtained by the NRP from the Camilli et al. (2003) recoded and reanalyzed data would be to use the parameter estimates from the regression model in which compromise weighting is used. Our best estimate of the  $a$  effects may be obtained by adding the constant from this model (.349) to half of the regression weight (because of the effect coding that was used) for  $TP2$ , or .188. We obtain an estimate for the effects of systematic phonics when compared to a no phonics control of  $.349 + .094$ , or  $d = 0.443$ . We can then use the parameter estimate for  $TP2$ , or .188, as our best estimate of the size of the  $c$  effect, or the difference between groups that received systematic phonics and those that received some phonics. If we assume that we had equal numbers of  $a$  effects and  $c$  effects to average, the best estimate of the overall average effect (without weighting by sample size) would be  $d = 0.316$ , or the average of .443 and .188. If there were more studies that evaluated the effect of systematic phonics compared to a no phonics control, the average would be closer to .443; if more studies evaluated the effect of systematic phonics versus a some phonics control, the average would be closer to  $d = 0.188$ . Although this average  $d = 0.316$  is smaller than the  $d = 0.41$  reported by the NRP, remember that this estimate represents an effect that has been adjusted for other study variables, such as the inclusion of language activities and tutors, so it should be smaller because the NRP estimates did not adjust for these moderators.

## Hypothesis 2

## Method

**Database.** To test the second hypothesis that combining different instructional activities was, on average, more effective, we used the Camilli et al. (2003) selection of studies and their coding of the NRP database and ran the regression model using the multilevel approach in Camilli et al. (2006). The analysis took into account the clustering of the data or the nonindependence of effects from the same study. It was not our intent to carry out a full multilevel model analysis with estimates of both fixed and random effects, but to replicate the regression analyses carried out by Camilli et al. (2006) on the modified database. Camilli et al. (2006) extended the work done in the 2003 reanalysis by recoding all of the studies for the level of systematic language activities in both the treatment and control groups using a 3-point rubric where a code of 0 indicated *no literacy activities*, 1 indicated *some literacy activities*, and 2 indicated *multiple language activities*.

**Procedures.** We deleted 25 effects from the total of 224 effects used in their analysis where there was neither some phonics nor systematic phonics instruction in the treatment group because we were interested in modeling treatment effects for phonics instruction and not for treatments that included no phonics. To facilitate interpretation of the regression parameter estimates, we recoded the *TP* variable into *TP\_di*, where 0 represented *some phonics instruction* and 1 represented *systematic phonics instruction*. We agreed that controlling for the presence of other instructional characteristics in both the treatment and control groups might help explain some of the heterogeneity found in the NRP study and would also potentially yield a less biased average effect.

Other than these two modifications, we set up the multilevel model analysis in the same way as Camilli et al. (2006) using the SPSS code for their analysis, which was available from the Web site for Camilli et al. (2003). We translated their code into SAS Proc Mixed code and then reran their analyses on their original variables and the full set of effects to verify that we were running the same multilevel model. We then ran this model on the smaller, recoded data set (from which the 25 superfluous effects had been deleted) and calculated the predicted effect size values from the resulting model for all combinations of our predictor variables: the amount and systematicity of phonics instruction in the treatment group (*TP\_di*), the amount and systematicity of language activities also present in the treatment group (*TL2*), the amount and systematicity of language activities in the control group (*CL2*), and whether or not the intervention was delivered one on one versus in small groups or classrooms (*Tutor*). The coding for *TL2*, *CL2*, and *Tutor* were included in the published database and were not changed.

## Results

The estimates of the fixed effects from our multilevel regression analysis are presented in Table 1. All of the treatment characteristics included in the model significantly predicted unique variance in the effect sizes. To evaluate the practical impact of these various treatments options alone and in combination, we combined, as in any standard regression-based prediction model, the coded values for the predictors with the regression weights (see Table 1) to calculate predicted mean effects for each combination of predictor

Table 1

*Fixed Effects From the Multilevel Model Modified From Camilli et al. (2006)*

Effect	Estimate	SE	<i>t</i>	<i>p</i>
Intercept	.306	.106	2.88	.007
<i>TP_di</i> <sup>a</sup>	.183	.089	2.06	.042
<i>TL2</i> <sup>b</sup>	.211	.106	1.98	.049
<i>CL2</i> <sup>c</sup>	-.213	.079	-2.71	.008
<i>Tutor</i> <sup>d</sup>	.424	.158	2.69	.008

Note. *df* = 36 for intercept; *df* = 158 for each of the other effects.

<sup>a</sup> Phonics in the treatment group: 0 = *unsystematic*, 1 = *systematic*.

<sup>b</sup> Language activities in the treatment group: 0 = *none*, 1 = *some*, 2 = *systematic*. <sup>c</sup> Language activities in the control group: 0 = *none*, 1 = *some*, 2 = *systematic*. <sup>d</sup> Intensity of instruction: 0 = *classroom- and small-group level*, 1 = *one on one*.

values. We then sorted the predicted values of the effect sizes from smallest to largest and present the mean predicted effect sizes along with the study characteristic codes in Table 2. Note that these analyses are based on the literature search by the NRP and the recoding of data by Camilli et al. (2006) and are therefore restricted to this body of studies.

Each row of Table 2 represents a potential combination of treatments and the expected effect size for that combination of treatments based on existing data. For example, the lowest *d* (-0.121), which may be found in the first row of the table, is the predicted value of *d* when there is some phonics in the treatment group, no language activities in the treatment group, no tutor, and systematic language activities in the control group. Under this condition a negative effect size favoring the control group is not surprising given the unique positive effect of systematic language activities that, in this comparison, are present in the control group but not the treatment group. Next, note the line in Table 2 in which all of the predictor values are 0 and the predicted effect size is *d* = 0.306. This line represents some phonics in the treatment group, no language activities in the control or treatment groups, and no tutoring. The value of predicted *d* for this scenario is equal to the intercept from our model. If we then move to the line where the *TP\_di* variable is 1 and all other predictors are 0, the predicted value of *d* is 0.488. Thus, if we compare a treatment group that receives systematic phonics, no tutors, and no additional language activities to a control group that also has no phonics or systematic language activities and is taught in small groups or whole classrooms, we can hypothesize that the treatment group would perform .488 standard deviations higher than the control group on the outcome assessment. This effect is simply the intercept plus the effect of moving one unit on the predictor while holding the other predictors constant.

Next, examine the row in Table 2 in which there is systematic phonics instruction plus 1:1 tutoring. The predicted effect is *d* = 0.913, a very large effect. If a practitioner already had a systematic phonics program in place, this table could be used to get an idea of the potential effect of adding tutoring or additional literacy components. In the first case, the hypothesized improvement would be approximately .425, or the difference between .913 and .488, not coincidentally the value of the beta weight for tutoring in this analysis. The hypothesized effect of adding both tutoring and systematic language instruction to an existing systematic phonics

program based on the body of studies in the NRP report as recoded by Camilli et al. (2003, 2006) is  $d = 1.34$ .

Note that the nonbolded rows in Table 2 represent combinations of the predictor variables for which there are no studies in the extant literature from which to estimate effects. The predicted  $d$  in this case is an interpolation based on the data in hand. We have bolded the rows that represent predicted effects based on actual effects in the meta-analysis and have included the number of effects and the number of studies for each of these rows. Obviously, we would have more confidence in estimating effects based on more substantial data than on only a few studies or on interpolation.

The estimates from Table 2 can be used to generate hypotheses of anticipated results that need testing in an experimental study. Caution should be exercised when comparing the effects of systematic phonics instruction to those for tutoring or language activities from Table 2. The set of studies identified by the NRP was the result of a search methodology designed to find all possible

studies that evaluated systematic phonics instruction using a randomized design or a high-quality quasi-experiment. This search was not designed to locate and include all possible studies evaluating the effect of using tutors to deliver instruction or of using language activities. Confidence in the magnitude of the systematic phonics effect is stronger because the NRP sought and identified the population of published studies.<sup>1</sup> The sample of tutoring and language activity effects contained within these studies is probably not the population of all such published effects and is also not a random sample from the population of all such studies; as a result, it is subject to selection biases. The effect on our results is that we

<sup>1</sup> Meta-analysis of the effect of group size do not support the greater efficacy of small-group tutoring in sizes of 1:1 versus 3:1 (Elbaum, Vaughn, Hughes, & Moody, 2000). Camilli et al. (2003, 2006) and the NRP compared 1:1 tutoring with the combined effects of small-group and classroom instruction.

should have less confidence in the precise magnitude of these effects or our ability to estimate the additive models laid out in Table 2. These cautions also apply to the conclusions reached by Camilli et al. (2003, 2006) and Hammill and Swanson (2006) to the extent that they are based on study characteristics other than the effect of systematic phonics.

### Hypothesis 3

#### Method

**Procedures.** Using the effect size estimates from the NRP report and different estimates of the incidence of reading difficulties, we used a variant of a binomial effect size display (Rosenthal & Rubin, 1982) to evaluate the practical significance of effect sizes of different magnitudes under different base rates of struggling readers. In this variant we used realistic base rates rather than the 50% base rate in the original formulation of binomial effect size displays.

**Statistical procedures.** To create these displays, we took advantage of the fact that the relation between two dichotomized variables may be summarized with the phi coefficient, which is equivalent to the correlation coefficient effect sizes used by Hammill and Swanson (2006). We created a  $2 \times 2$  table to represent the relation between a phenomenon of interest with two levels (high school dropout vs. high school completion) and a treatment with two levels (treatment vs. control). We placed the existing base rate for the phenomenon into the control level of the treatment and then, for a given level of phi, calculated the frequency of the phenomenon in the treatment group required to obtain that level of phi. Table 3 contains a table of symbolic frequencies to be used in conjunction with the formula for phi to solve for the unknown frequency for a given base rate and given phi:

$$\Phi = (ad - bc) / \sqrt{efgh}.$$

Using  $a$  through  $h$  in this equation, if we assume a value for  $c$  based on our knowledge of the base rate of a given phenomenon, and set  $g$  and  $h$  equal to each other, we can solve for the value of  $d$  that would correspond to any given phi value. For our examples, we chose total frequencies within the treatment and control to be equal ( $n = 10,000$  each) and large enough to allow us to calculate frequencies in the treatment group in whole numbers. We used our assumed base rate to obtain the frequencies  $a$  and  $c$ . If the base rate of high school noncompletion were 10%, we would set  $a$  equal to 9,000 and  $c$  equal to 1,000 and solve for the value of  $d$  associated with a given level of phi.

**Hypothetical scenarios.** We created three hypothetical examples addressing the potential impact of even small effects within

the context of reading instruction. In Scenario 1, we used the rate of at-risk readers in early intervention programs, commonly (but somewhat arbitrarily) estimated at 20% (Torgesen, 2000), as the characteristic we would like to change. In Scenario 2, we reduced the effect size in Scenario 1 and lowered the base rate to the high school noncompletion rate of 10% (Laird, DeBell, & Chapman, 2006) as the phenomenon we would like to reduce. In Scenario 3, we maintained the small effect size in Scenario 2 but increased the base rate to represent the number of struggling readers in the United States, which was cited as up to 40% by Hammill and Swanson (2006; see Shaywitz, 2004).

#### Results

In the first scenario, consider  $d = 0.48$ ,  $r = .23$ , an effect size called "small" by Hammill and Swanson (2006). This effect was chosen because it was the effect for typical achievers in first grade from the NRP report. In Scenario 1, assuming a sample of 20,000 (half treatment, half control) and a base rate of 20% of at-risk readers who participate in a reading program with a predicted  $d = 0.48$ ,  $r = .23$ , Table 4 shows a cross-tabulation of treatment and at-risk classifications. An intervention that results in a phi coefficient of .23 between the treatment and classification is consistent with an expected frequency of at-risk readers in the intervention group of 5%, a substantial decrease from 20%.

Similarly, consider an intervention that yields an effect size  $d = 0.23$ ,  $r = .11$ , with respect to the high school dropout rate (see Table 4). We selected this effect size, the smallest significant effect reported in the NRP meta-analysis, because not only was it labeled small by Hammill and Swanson (2006), but it is also close to the Cohen (1988) heuristic for a small effect size. Assuming a 10% high school dropout rate without an intervention (Laird et al., 2006), an intervention that correlates with dropout status at the  $r = .11$ ,  $R^2 = .012$ , level could result in a reduction in the dropout rate from 10% to 4.5%.

Finally, consider an intervention for which we expect a small effect of  $d = 0.23$ ,  $r = .11$ , and set our base rate for struggling readers at 40%. Adjusting the base rate so that it is higher should reduce the potency of an intervention with a small effect size. Even with an intervention with this small effect size, we could hypothesize a reduction in incidence of poor readers from 40% to 30% (see Table 4).

### General Discussion

There are three major conclusions from our assessment of Camilli et al. (2003, 2006) and Hammill and Swanson (2006). First, in terms of the first hypothesis, the conclusions of the NRP report are not contradicted by the two reanalyses of Camilli et al. (2003, 2006). The comparisons by Camilli et al. (2003, 2006) ask questions that are different from the primary question asked by the NRP, but the results of the two sets of analyses can be reconstructed to yield comparable effect sizes for the effects of systematic phonics versus either unsystematic phonics or no phonics controls when the same study parameters are estimated. When the effect sizes have been adjusted for study moderators, as in Camilli et al. (2003, 2006), the estimates are expected to be lower than the NRP estimate because the other treatment characteristics tend to improve performance (i.e., are positively related to the effect size)

Table 3  
Example of Symbolic Frequencies to Be Used With the Formula for Phi to Solve for the Unknown Frequency for a Given Base Rate and Phi

Variable	Control	Treatment	Total
High school completion	$a$	$b$	$e$
Noncompletion	$c$	$d$	$f$
Total	$g$	$h$	$a + b + c + d$

Table 4  
*Binomial Effect Size Display for 10,000 Students in Scenarios 1, 2, and 3 After Intervention*

Group	Classification	No intervention	With intervention
Scenario 1			
At-risk readers <sup>a</sup>	No	8,000	9,500
	Yes	2,000	500
Scenario 2			
High school dropouts <sup>b</sup>	No	9,000	9,550
	Yes	1,000	450
Scenario 3			
Struggling readers <sup>c</sup>	No	6,000	7,000
	Yes	4,000	3,000

*Note.* Scenario 1: base rate = .20,  $d = 0.48$ ,  $r = .23$ ; Scenario 2: base rate = .10,  $d = 0.23$ ,  $r = .11$ ; Scenario 3: base rate = .40,  $d = 0.23$ ,  $r = .11$ .  
<sup>a</sup> Incidence of at-risk readers reduced from 20% to 5%. <sup>b</sup> Incidence of high school dropouts reduced from 10% to 4.5%. <sup>c</sup> Incidence of struggling readers reduced from 40% to 30%.

and because the vectors of study characteristics are not orthogonal to one another. If the estimates are directly compared, the key is to estimate the same effect size across the different studies. An effect size is always a comparison of different conditions with one another (see Figure 1). The NRP and Camilli et al. (2003, 2006) estimated effects from different comparisons.

Second, Camilli et al. (2003, 2006) showed that both phonics and language instruction, as well as tutoring, impacted reading outcomes. They questioned whether it was accurate to assume that phonics instruction was the core of many of the programs represented in the NRP database, especially interventions in the control groups. These findings support the NRP contention that reading programs need to be comprehensive by providing estimates of the unique contributions of different factors that moderate the impact of phonics. To get larger effect sizes, reading instruction must be comprehensive and contain literacy components beyond phonics, especially when the diversity of students in classrooms and local instructional contexts are considered. Thus, in terms of the second hypothesis, reanalyses of the NRP report show that larger effects may occur in association with combining different components of reading instruction. Within the modified NRP corpus of studies, systematic phonics was associated with larger effects than no or some phonics, but the effects tended to be small to moderate and variable across studies, and much of the explainable variability in effects (i.e., that not associated with sampling error) was not accounted for by the intervention characteristics included in the model. The addition of literacy components that presumably support fluency and comprehension, as well as tutoring, was associated with larger effects. However, larger effects were associated with systematic phonics, regardless of the levels of systematic language activities and tutoring. Within the modified NRP corpus of studies, the largest effects were associated with the combination of systematic phonics with additional language and literacy activities and one-on-one tutoring.

Third, whether we characterize  $d = 0.41$  as moderate or small, the evaluation of Hypothesis 3 shows that even small effect sizes may be of sufficient magnitude that they could be associated with significant reductions in the incidence of reading problems. Hammill and Swanson (2006) utilized Cohen's rules of thumb for planning studies as thresholds for determining the practical significance of effect sizes but did not take into account context and base rates in their dismissal of small effect sizes, essentially committing a Type II error. Although they were correct in suggesting that additional variability is unexplained, it is an inappropriate extrapolation to suggest that the amount of explained variability is not practically significant. In Scenario 1, with a medium effect and a medium small base rate, the hypothetical intervention reduced the incidence of struggling readers from .20 to .05, for a reduction of 75%. In Scenario 2, with a small effect and a lower base rate than Scenario 1, the hypothetical intervention reduced the incidence from .10 to .045, for a reduction in struggling readers of 55%. In Scenario 3, with the same small effect as Scenario 2 and a high base rate, the given effect size was associated with a reduction in struggling readers from .40 to .30, or 25%. These examples show that the impact of even small effect sizes may be practically important, especially when coupled with low base rates of the phenomenon of interest. The next step in placing these effects into a context involves computing the costs associated with delivering a given intervention with the benefits expected from moving some number of individuals from one category to another and comparing these costs with expected benefits. This step is outside of the bounds of this article, and, in fact, because costs and benefits are context dependent, the practical significance of a given effect size might be decided on a location-by-location basis. However, because reading instruction is routinely provided to students in schools, the costs in changing instructional emphases should be relatively small compared to the overall costs already in place for teaching children to read. The effect size and the base rates used in our examples are comparable to situations that exist with different school settings and interventions.

Altogether, these results support approaches to reading instruction that are more comprehensive and, for alphabetics, approaches that are more explicit and in which the knowledge is directly shared relative to those in which knowledge must be inferred by students. Whether these principles extend beyond just the effects of phonics instruction cannot be established from the NRP report or Camilli et al. (2003, 2006), although other reviews support more explicitness for fluency and comprehension (Pressley, 2005). In reaching this conclusion, we note that these pedagogical principles exist on a continuum and should not be dichotomized. In examining this continuum for instruction involving the alphabetic principle, it may be that the more important component is explicitness and the deliberate attempt to instruct the child as opposed to a scripted approach to phonics, especially if the child is at risk for reading difficulties or is struggling to learn to read. Indeed, both the NRP and Camilli et al. (2006) concur in estimating larger effects of systematic phonics for students who are struggling readers, findings supported by recent experimental studies that formally manipulate explicit instruction in relation to child characteristics. For example, Connor et al. (2007) found that more time in phonics instruction is beneficial to students weak in alphabetic knowledge; conversely, more time on comprehension instruction

leads to better outcomes in students weak in vocabulary instruction.

To illustrate the difference in scripted versus explicit, Torgesen et al. (2001) compared the efficacy of a highly scripted reading program with a clearly defined scope and sequence with an approach that taught the alphabetic principle explicitly but spent more time reading and writing in context. There were no significant differences in outcomes for a group of elementary school children with severe reading disabilities (see also Wise, Ring, & Olson, 2000). Mathes et al. (2005) compared two comprehensive small-group tutorial interventions based on (a) a direct instruction model with a scripted lesson plan and well-developed scope and sequence with use of decodable text; and (b) a guided reading intervention in which instruction in the alphabetic principle was explicit (i.e., based on a plan for introducing phonics elements and in which the information was directly presented to the child) and done for about 20% of the instructional period, but unscripted and with the use of leveled texts instead of decodable texts. No major differences in reading outcomes for first graders at risk for reading difficulties were apparent when these two comprehensive programs were compared.

These examples show that the explicitness of instruction may be more important than systematic, scripted lessons in accounting for the effect of systematic phonics. Creating a scope and sequence, using decodable text, and engaging in other ways of systematizing instruction make instruction explicit, but explicitness can be achieved in other ways. Where a teacher operates on the instructional continuum may depend on factors like preparation, experience, the base rate of struggling readers, the school context, and related factors. However, teachers need to be intentionally clear about how the alphabet relates conventionally to sound segments in speech. The supporting materials that are used may vary depending on teacher and student knowledge and skills.

In contrast to the seemingly endless political and ideological commentaries about the purposes and findings of the NRP study, Camilli et al. (2003, 2006) and Hammill and Swanson (2006) have advanced the field by focusing on the data and the need for replication and confirmation of the NRP findings. Adjudication of the issues raised by the NRP report through attempts at replication and continued experimentation can help move the field beyond the simplistic instructional dichotomies that have plagued theory and instruction on reading toward richer and more complex approaches that will enhance reading proficiency for all children. Nonetheless, our analyses of Camilli et al. (2003, 2006) and Hammill and Swanson do not support the belief that the NRP misrepresented their findings or misled policymakers and the educational community (Allington, 2006). The NRP relied on empirical synthesis (meta-analytic methods) for the interpretation of a large body of research. The NRP report explicitly stated the criteria for including studies in the meta-analysis and was subjected to peer review prior to its release to the public.<sup>2</sup> Our reanalysis of the NRP findings confirm their conclusions concerning phonics instruction but must be understood in the context of the need for comprehensive approaches to reading instruction. As the NRP (NICHD, 2000, p. 2-97) stated, "Phonics instruction is never a total reading program," and it "should be integrated with other reading instruction."

These conclusions lead to what we believe should be the reading community's vision of an effective reading program. That is, comprehensive instruction involves explicit instruction in the al-

phabetic principle, explicit instruction in comprehension and vocabulary, and active engagement of the child to develop fluency (Pressley, 2005; Snow et al., 1998). Few in the reading community would disagree that this task is arduous and hardly begun, and the next step is advancing beyond the findings of the NRP and other consensus reports. When phonics is systematic (as defined by the NRP), additional well-conceived literacy activities (as defined by Camilli et al., 2003, 2006) are added, and tutoring is used to increase intensity, the effect sizes may be larger than for any of these components in isolation. That is the important message of the NRP report, Camilli et al. (2003, 2006), and Hammill and Swanson (2006). Although it seems difficult to move beyond the historic dichotomy of reading instructional approaches, it is time to embrace comprehensive approaches to reading instruction and work toward determining how to integrate different components of reading instruction into classroom practice so that the diversity of students and their individual needs can be addressed.

<sup>2</sup> Camilli et al. (2006, p. 30) were in error when they indicated that the NRP report was not subjected to peer review prior to its release (P. McCordle, personal communication, February 21, 2007). In suggesting that the NICHD change procedures for producing meta-analyses, there is a misunderstanding. Consensus reports at the National Institutes of Health are usually done by the Office of Medical Applications of Research (OMAR), which convenes panels of scientists to produce consensus reports. Although the NRP was congressionally mandated, it preceded OMAR in deciding to use meta-analysis. Procedures for conducting syntheses, including the use of meta-analysis, are determined by the specific committee, not the National Institutes of Health or OMAR.

Chinese University of Hong Kong

The present study examined the role of verbal working memory (memory span, tongue twister), 2-character Chinese pseudoword reading, rapid automatized naming (letters, numbers), and phonological segmentation (deletion of rimes and onsets) in inferential text comprehension in Chinese in 518 Chinese children in Hong Kong in Grades 3 to 5. It was hypothesized that verbal working memory, together with a small contribution from the other constructs, would explain individual variation in the children's text comprehension. Structural equation modeling and hierarchical multiple regression analyses generally upheld the hypotheses. Though Chinese pseudoword reading did not play an important mediating role in the effect of verbal working memory on text comprehension, verbal working memory had strong effects on pseudoword reading and text comprehension. The findings on the Chinese language support current Western literature as well as display the differential role of the constructs in Chinese reading comprehension.

*Keywords:* Chinese text comprehension, verbal working memory, pseudoword reading

Children's reading comprehension has been shown to be influenced by their verbal working memory (Cain, Oakhill, & Bryant, 2000, 2004); their rapid, automatic decoding of words (Perfetti, 1985); their phonological skills (Shankweiler, 1989); and a range of cognitive and metacognitive strategies, such as monitoring comprehension, activating background information, integrating multiple strategies of questioning, clarifying and searching for information, identifying story themes, summarizing main points, and predicting outcomes (e.g., Oakhill, Cain, & Bryant, 2003; Perfetti, Landi, & Oakhill, 2005; Williams et al., 2002).

Che Kan Leong, Department of Educational Psychology and Special Education, University of Saskatchewan, Saskatoon, Saskatchewan, Canada, and Department of Educational Psychology, Chinese University of Hong Kong, Shatin, Hong Kong, China; Shek Kam Tse and Ka Yee Loh, Faculty of Education, University of Hong Kong, Hong Kong, China; Kit Tai Hau, Department of Educational Psychology, Chinese University of Hong Kong, Shatin, Hong Kong, China.

We thank the children, their parents, and their teachers in the two schools in Hong Kong for their participation in the project, and we thank the research assistants for their work with the children. Che Kan Leong is grateful to the Social Sciences and Humanities Research Council of Canada for its support through Research Grant 410-01-0059. Shek Kam Tse, Ka Yee Loh, and Kit Tai Hau acknowledge the assistance of internal university grants.

On Chinese children's reading acquisition and development in Chinese, almost all the studies are on phonological sensitivity, with some data on orthographic and morphological processing in relation to reading characters or two-character words (e.g., Ho & Bryant, 1997; McBride-Chang et al., 2005; McBride-Chang & Ho, 2005; Shu, Chen, Anderson, Wu, & Xuan, 2003; Siok & Fletcher, 2001). There are few experimental studies on reading comprehension in Chinese elementary school students. Drawing on the various studies with children using alphabetic language systems as background, we examined the relative contribution of verbal working memory, two-character Chinese pseudoword reading, rapid naming, and phonological sensitivity skills to Chinese text comprehension in a sample of 518 elementary school Chinese students in Hong Kong. We hypothesized that Chinese children's text comprehension in Chinese, as assessed by their short, written answers to open-ended inferential questions on literal aspects, coherent links of text, and application of information in a novel situation, would be primarily influenced at the lower level by verbal working memory. We also examined whether the effect of verbal working memory on text comprehension was mediated by Chinese pseudoword reading (Holmbeck, 1997). To a much smaller extent, rapid naming and onset-rime phonological segmentation tasks might also play a role. The appropriate statistical techniques used to examine the relative contributions of the cognitive and linguistic tasks were a set of hierarchical multiple regression analyses. To test mediated effects, we used structural equation modeling, as recommended by Holmbeck (1997).

## Comprehending Chinese Text in Relation to Cognitive and Linguistic Skills

The emphasis of this report is on text inferencing and on some lower level cognitive and linguistic skills that might influence higher level text comprehension. Inference was defined operationally as encoding the information activated during reading, which may not be explicitly stated in the text (Kintsch, 1994; McKoon & Ratcliff, 1989; see also Singer, 1994; van den Broek, 1994). In Hong Kong, what standardized language achievement tests exist are short, omnibus tests with only a small component on reading comprehension. Thus, text comprehension tests needed to be specially devised on the basis of current theory of comprehension, with a certain amount of face validity to ensure acceptance by teachers, students, and parents (Kintsch & Kintsch, 2005). This latter aspect is particularly important, in that a recent study showed that participants could answer the questions for a well-established standardized comprehension test with above-chance accuracy without reading the passages (Keenan & Betjemann, 2006). In the present study, attempts were made to take into account the findings by Kintsch and Kintsch, Keenan and Betjemann (2006), and others. The logic of the text comprehension task is outlined below, while the details are provided in the *Tasks and Procedure* and *Results* sections.

A total of eight short text passages were specially devised. Each text passage was followed by three kinds of questions: one each on literal inference, coherence inference, and elaboration inference. Literal inferencing is concerned with the surface level of comprehension. Coherence inferencing relates to the whole text and is a function of the local, cohesive nature of individual events, which, in turn, involves linguistic devices such as anaphoras, intersentential connectives, and other discourse pointers (Halliday & Hasan, 1976; Sanders, Spooren, & Noordman, 1992). Elaborative inferencing refers not only to information in the propositions or concepts but also to probable expectations about subsequent information that is inferred from the text and knowledge of the comprehender (Kintsch, 1994; Noordman & Vonk, 1999). Examples of these kinds and levels of inferencing are further discussed in the *Tasks and Procedure* section. In the next several sections, we discuss the role of verbal working memory, word reading, rapid naming, and phonological segmentation in text comprehension.

### Verbal Working Memory

*Working memory* refers to processing resources of limited capacity that individuals need to maintain information while simultaneously acting on the same or other information, and it requires the coordination of both storage of information and processing of additional and sometimes unrelated information (Baddeley, 1986). Verbal working memory tasks generally require children to hold increasingly complex verbal information in memory while responding to questions about the tasks and thus play a role in activating information from long-term memory and in making inferences in text comprehension. Moreover, phonological processing information at the word or subword level has an effect on working memory storage and, indirectly, on reading comprehension.

Following from the early, influential work of Daneman and Carpenter (1980), a number of studies have further shown that a

measure of reading span makes a unique contribution to measures of reading comprehension (e.g., Cain et al., 2000; Cain, Oakhill, & Bryant, 2004; Daneman & Carpenter, 1983; Seigneuric & Ehrlich, 2005; Seigneuric, Ehrlich, Oakhill, & Yuill, 2000). The general idea is that participants have to understand the meaning of each of a group of unrelated sentences to be able to answer a comprehension question (the processing aspect) and, at the same time, to recall the last words in the sentences (the storage aspect). Skilled comprehenders may allocate more working memory resources to text comprehension than to word recognition as compared with less skilled readers (Swanson & Berninger, 1995). Given similar levels of background knowledge, good comprehenders tend to make more integrative inferences than poor comprehenders, who are constrained by working memory to build mental models of text (Oakhill, Cain, & Yuill, 1998). Further, poor comprehenders show specific difficulties in the verbal domain of working memory, which, in turn, relate to impairment in semantic and syntactic skills (Nation, Adams, Bowyer-Crane, & Snowling, 1999). In a meta-analysis involving 77 studies and over 6,000 participants, Daneman and Merikle (1996) reaffirmed the original Daneman and Carpenter (1980) study's finding that verbal process plus storage measures of working memory capacity are good predictors of language comprehension. The process plus the storage span measures were used in the present study.

### Chinese Pseudowords

The notion and characteristics of Chinese pseudowords are quite different from those in English. Pseudowords in English are pronounceable nonwords (e.g., *bave*) and have been shown to correlate highly with real word recognition and reading comprehension (e.g., Rack, Snowling, & Olson, 1992). Children's level of skill in reading pseudowords is an indication of their phonological processing ability, which is critical in reading alphabetic orthographies. Does similar logic apply to reading pseudowords in Chinese?

In the first place, a distinction must be made between a Chinese character (*zi*) as a basic orthographic unit or graphic symbol and a word (*ci*), consisting usually of two or more characters. The basis of compositionality of characters is the corpus of about 560 foundational *bujians*, which subsume about 212 *radicals*, with constituent phonetic and semantic cues as aids in reading and spelling and in accessing dictionaries (Chinese National Language Committee, 1998). A character almost always corresponds to a morpheme (not a phoneme) in the spoken language, whereas a word is the smallest independent unit of meaning and is polymorphemic (Leong, 1997). For example, the word *library* consists of three characters meaning *picture*, *book*, and *institution*.

In the present study and in a study by Leong, Cheng, and Tan (2005), two-character Chinese pseudowords, or, strictly, *pseudocis*, were used. For these two-character pseudowords, each of the constituent characters was a real, pronounceable character, but their combination yielded a pronounceable but meaningless Chinese word. This method of constructing Chinese pseudowords gets around the issue of pronounceability, since each constituent character is pronounceable. More important, unlike pseudowords in English, the focus is on the children's correct oral reading of each of the two characters singly and in combination by utilizing

phonetic, orthographic, morphological, and meaning cues. The mechanism of retrieving all linguistic cues from long-term memory to address the phonology in pronouncing the two-character pseudowords may approximate the mechanism in retrieving, integrating, and interpreting information in short Chinese text materials.

### *Rapid Automatized Naming (RAN)*

The early notion by Denckla and Rudel (1974) of “lack of automaticity” as a correlate of reading and its difficulties and the resultant RAN test with practical applications have been substantiated and refined in a number of recent studies. While there have been different studies and debates on the continuous format (presenting all items) or discrete format (presenting items individually) of task presentation (Denckla & Cutting, 1999; van den Bos, Zijlstra, & Spelberg, 2002) and different arrangements of visual arrays of the items (Compton, Olson, DeFries, & Pennington, 2002), it has been shown consistently that RAN discriminates between good and poor readers and adds uniquely to normal elementary reading beyond phonological sensitivity and memory tasks.

RAN, with its presymbolic component (colors and objects) and symbolic component (numbers and letters), is part of an efficient and rapid phonological retrieval process, and the underlying process relating RAN performance to word reading is a complex one (Compton et al., 2002; Denckla & Cutting, 1999; van den Bos et al., 2002). A recent neuroimaging study of 12 adults showed that RAN taps into the same neural network required for complex reading tasks and that the RAN letter task has greater predictive ability because it is sensitive to the posterior areas associated with the reading network (Misra, Katzir, Wolf, & Poldrack, 2004).

### *Onset–Rime Phonological Segmentation Tasks*

On the question of the involvement of phonology in reading Chinese, it is often assumed (erroneously) that reading Chinese characters relies primarily on “visual” skills and orthographic analysis and that the processing route is more from graphic symbols to meaning. While the square-shaped Chinese characters, which occupy the same geometric space for each symbol, are visually complex as compared with English words, there is little support for the assertion that the identification of characters is from graphic symbols directly to meaning. Research using different experimental paradigms, such as priming and backward and forward masking, has shown that phonology is an interactive constituent part in identifying Chinese characters and is activated early, rapidly, and at the moment of recognizing orthographic shapes (“at lexicality”; Spinks, Liu, Perfetti, & Tan, 2000; Tan & Perfetti, 1998, 1999). Furthermore, according to the universal writing system constraint, all writing systems encode language, and according to the universal phonological principle, the activation of word pronunciation occurs across all writing systems. In addition, the effect of phonology is robust as tested with event-related potentials and functional MRI (Perfetti, 2003; Perfetti & Liu, 2005; Perfetti, Liu, & Tan, 2002).

In Chinese, there is evidence that onset–rime deletion, rather than phonemic awareness, of Chinese characters predicts Chinese

character and word reading (Siok & Fletcher, 2001). This emphasis on onset–rime deletion, rather than segmental phoneme deletion, is in keeping with psycholinguistic analysis that Chinese is basically paradigmatic and not so much segmental and that the basic unit of the character is coterminous with the syllable with its onsets and rimes (Leong, 1997; Wang, 1985). Do these results of the role of onset–rime deletion go beyond character and word reading? Do they apply to reading comprehension in Chinese? Quite possibly the incorporation of phonological segmentation tasks at the beginning phase in reading in Chinese can explain some additional individual variations in reading comprehension in Chinese (McBride-Chang, Bialystok, Chong, & Li, 2004).

## Method

### *Participants*

A total of 518 children in Grades 3, 4, and 5 from two elementary schools in Hong Kong, who were rated as average relative to the territory-wide population in students’ academic performance and their family’s social economic status, took part in the study. In brief, Hong Kong Grade 6 students are broadly classified into three bands according to their territory-wide academic examinations performance, with Band 1 being the highest, Band 2 average, and Band 3 the lowest. The students in the two schools were mostly in Band 2 and, hence, considered to be average in academic performance. In terms of socioeconomic status, the families of these two schools could be rated as at the median household income level according to the 2006 Hong Kong population by census (Hong Kong Census and Statistics Department, 2006). The schools and their students were thus selected on the basis of average academic performance and median socioeconomic status territory-wide, and the students all consented to take part in the study as volunteers.

There were 140 Grade 3 students from six classes ( $n_{\text{boy}} = 82$ ,  $n_{\text{girl}} = 58$ ;  $M_{\text{age}} = 9.06$  years,  $SD_{\text{age}} = 0.44$  years), 187 Grade 4 students from seven classes ( $n_{\text{boy}} = 110$ ,  $n_{\text{girl}} = 77$ ;  $M_{\text{age}} = 10.08$  years,  $SD_{\text{age}} = 0.47$  years), and 191 Grade 5 students from nine classes ( $n_{\text{boy}} = 108$ ,  $n_{\text{girl}} = 83$ ;  $M_{\text{age}} = 11.21$  years,  $SD_{\text{age}} = 0.69$  years). For the total sample, the mean age was 10.22 years ( $SD = 1.02$  years). The group tasks were administered in the classrooms of the students, and the individual tasks were administered in quiet rooms in the school, all in random order. Three full-time and six part-time Chinese-speaking senior research assistants from a local university were given several days’ intensive training on the rationale of the project, the reasons and designs of the group and individual tasks, and specifics of administration before their field work in the schools. These assistants all had experience in working on other projects and, during the intensive interactive training sessions, also offered considerable advice on the tasks, which were further modified and fine-tuned before their administration. These experienced assistants were carefully supervised by Shek Kam Tse and Ka Yee Loh to ensure high fidelity of the field work.

### *Tasks and Procedure*

*Text comprehension.* Because there is no standardized reading comprehension tests for Hong Kong Chinese children, this task had to be specially designed and its psychometric properties as-

certained. Eight short text passages were adapted, modified, and rewritten in traditional (complex) Chinese characters from the most recent and currently used series of Chinese text books for Grades 3 to 6 published by a leading textbook publisher in Beijing. These books were selected as the basis for the text comprehension passages because the original sources were approved by the national textbooks committee of China and the characters and words used were based on statistical analyses of the corpus (Beijing Language Institute, 1984).

Of the eight rewritten text passages, four were narrative pieces (Passages 1, 2, 3, and 8, titled "Pearl of the Orient [Hong Kong]," "Spear and Shield," "Shutting the Pen After Losing the Goat," and "Moonlight Sonata," respectively); three were expository (Passages 4, 6, and 7, titled "The Great Wall [of China]," "Peanuts," and "Nobel," respectively); and one was a poem from the well-known poet Li Po (Passage 5, titled "[Seeing Friend Off]"). These eight short pieces, ranging in length from 6 to 13 sentences, were carefully balanced in syntactic complexity in accordance with general principles in applied linguistics in Chinese (Chao, 1968; Wang, 1985). The contents were familiar to 9- to 11-year-old Chinese children to minimize the impact of background knowledge. The text comprehension task, with the eight passages followed by three open-ended inferencing questions each, was administered as a written task to the whole class of students in 40 min, plus about 8–10 min for two short practice examples to explain clearly the aim of drawing inferences from text. The children were told to read silently each printed text passage, to concentrate on making inferences, and not to worry about sentence construction and spelling. Differential credits of 0, 1, 2, and 3 were awarded according to the implausibility, shallowness, or depth of the short written answer to each question. The maximum score for the whole task was 72 (8 passages  $\times$  9 marks maximum for three questions per passage).

The principles of scoring the written answers on the basis of transforming knowledge and not merely retelling it (Bereiter & Scardamalia, 1987), of explanatory and not just descriptive answers, and of "envisionment" of text worlds (Langer, 1986) characterized the approach to assessing text comprehension in the present study. Passage 2, "Spear and Shield," is shown in the Appendix with its English translation. The first question, on the different uses of the spear and the shield, was an example of literal inferencing; to secure a score of 3, students had to explain briefly the offensive and defensive uses of the two kinds of weapons. To answer the elaboration question, on the reason for the attack tank being a powerful weapon, students had to integrate the different concepts to go beyond the information given to attain the top score of 3. The third question, about giving a suitable title and giving reasons for the choice, was an example of coherence inferencing, and students had to draw on cohesive concepts in the passage as a whole to explain how the ideas of the spear and the shield could evolve into the powerful attack tank. Another concrete example came from Li Po's poem on seeing a friend off; the first question, on the direction of the house where the farewell was said, was given in the first line and was an example of literal inferencing. The question on the imagery of the firework exemplified coherence inferencing. The question on the poet's feeling in bidding a good friend farewell drew on the emotive aspect and required elaboration and integration of different concepts conveyed explic-

itly and implicitly in the short poem. To score the maximum of 3 on the question on the firework, participants had to recognize and explain that the line "Firework haze in Yangzhou in the third moon" suggests spring, fog in March, and the prosperity of Yangzhou.

To ensure consistency of scoring, two research assistants independently scored each set of written protocols according to the marking rubrics explained above. Internal consistency, as measured by Cronbach's alpha, for the eight passages was .908, indicating that these passages as a whole and the answers to the comprehension questions were consistent and reliable. On the basis of the genre and structure, the mainly narrative pieces (Passages 1, 2, 3, and 8) constituted Text Comprehension 1. The interrater reliabilities for the answers to the 12 questions of these four passages were, respectively, .854, .876, .850, and .709. The mainly expository pieces (Passages 4, 5, 6, and 7) formed the second indicator, Text Comprehension 2. The interrater reliabilities for the 12 answers to the questions of these four passages were, respectively, .702, .792, .716, and .657.

To establish some face validity of the text comprehension passages and to ensure that participants could not arrive at the written answers without reading the passages (see Keenan & Betjemann, 2006), we asked a randomly selected group of 53 Grade 4 students ( $M_{\text{age}} = 9.00$  years,  $SD_{\text{age}} = 0.24$  years) who were not in the study simply to write down their answers to the same comprehension questions without having read the passages. A further group of 33 university students ( $M_{\text{age}} = 22.76$  years,  $SD_{\text{age}} = 2.23$  years) was likewise asked to answer the questions without the benefit of reading the passages. These 53 sets of just answers from the Grade 4 children and the 33 sets of just answers from the university students, which they gave without reading the passages, were all scored by the same assistants who worked on the total sample of 518 students. The results of the passage-dependent reading comprehension tasks from these two different groups are discussed in the Results section.

*Memory span task.* The memory span task as a main indicator of verbal working memory for children was modeled after the sentence span task of Swanson (1992), which derives its rationale and format from the influential Daneman and Carpenter (1980) work. A total of 13 sets of two, three, four, and five sentences, all unrelated in meaning, were read orally by the experimenter to the participants as a group task. Participants were asked to listen to each set of sentences and to write down their short answers to a comprehension question and, at the same time, the last word in each sentence of the set. A translated example from a two-sentence set is "The sun gives out bright light. I helped mom do a hard job." The expected answer to the comprehension question "What kind of light does the sun give out?" should be "bright," and the last words should be "light, job." The total testing time for this task was about 25 min, which was found to be ample, and all the answers were scored independently by two assistants. One mark was awarded for each correct answer to each comprehension question and each word correctly named, with a maximum score of 60 (13 answers and 47 last words). The internal consistency Cronbach's alpha of the total answers was .930, while the interrater reliability was .904. A further example of the task is provided in the Appendix.

*Tongue-twister task.* The Chinese tongue-twister task, which is a popular game for both young and old Chinese alike, is based

on the logic that automatic phonemic interference arises more from working memory processes and much less from articulatory processes (Zhang & Perfetti, 1993), and this finding makes it a suitable task to subserve the construct of verbal working memory. Chinese tongue twisters have the added advantage that there is no confounding between phonological and visual–orthographic similarity, and this should produce a stronger tongue-twister effect than in English. Zhang and Perfetti (1993) reported a robust tongue-twister effect for visually presented tongue-twister short stories in Chinese, compared with control stories. These results upheld the phonemic nature of the tongue-twister effect and the activation of the phonological code to support reading comprehension in Chinese.

The present tongue twisters were designed with sets of nonsegmental phonemes, such as alveolar fricatives (/s/ and /z/), alveolar stops (/t/ and /d/), and bilabial and velar stops (/b/ and /p/, /g/ and /k/). The spoken sentences were modifications of those used by Leong and Tan (2002) with Putonghua-speaking children in Beijing, later modified to accommodate Cantonese speech sounds used by children in Hong Kong (see Leong et al., 2005), and were further refined for the present study.

There were eight sets of sentences drawing on discriminating Cantonese speech sounds with their different lexical tones. An example of a two-sentence set of tongue twisters (with their Cantonese lexical tones indicated in square brackets) is “Silzi[2]saanlsoeng[5]silasnlzi[2], saanlzi[2]mun[4]cin[4]-sei[3]silzi[2]saanlzi[2], Sannlzi[2]si[6]sim[4]zi[2], silzi[2]-si[6]sek[6]silzi[2].” The translation is as follows: “Lion Temple is on top of Lion Hill; there are four lion [statues] in front of the temple. The temple is a Buddhist temple; lion statues are stone lions.” The general idea in this actual item was to play on the Cantonese onsets of /s/ and /ts/. A further example is shown in the Appendix. Each child was asked to listen to each spoken sentence and to repeat it verbatim at his or her own pace in the same word order and the same lexical tone as spoken. The tongue twisters were scored according to the number of characters repeated in the correct order and tone, and the maximum was 170. Testing time was about 15 min. Internal consistency Cronbach’s alpha was .808.

*Chinese pseudoword reading.* The Chinese pseudoword reading task consisted of 72 items (sample items appear in Appendix), with the characters all carefully selected from the same series of textbooks, published by People’s Education Publishing in Beijing, on which the comprehension passages were based. Each of the two constituent characters was a real character, but their combination yielded a pronounceable, meaningless Chinese pseudoword. The 72 two-character pseudowords task was refined from that used by Leong et al. (2005) with 157 Chinese students in Grades 4 and 5 in Beijing and Hong Kong, which, in turn, was derived from the 36 most discriminating items from a 72-item task for Grade 4 children and another 36 most discriminating items from a 72-item task for Grade 5 children. The refined 36 items for Grade 4 constituted subtask Pseudoword 1 (PW1), and the refined 36 items for Grade 5 formed subtask Pseudoword 2 (PW2). PW1 and PW2 also took into account such linguistic principles as printed frequency and lexical tones of the characters (Chao, 1968). Each child was asked to read aloud correctly and rapidly each decontextualized two-character pseudoword or pseudo-*ci*. Total testing time was about 7 min per child. A credit of 1 was given for each character identified

and read correctly, and the maximum score for both PW1 and PW2 was 144. Cronbach’s alpha coefficient for the total task was .937.

*RAN.* From the studies discussed earlier and the factor analytic finding by van den Bos et al. (2002) of the separability of presymbolic and symbolic components (see also van den Bos, Zijlstra, & van den Broeck, 2003), the alphanumeric part of RAN (one for letters of the alphabet, and one for Arabic numbers) was administered individually to the participants. The format used was the alternative version (RAN alternative) of Compton et al. (2002), because of their finding that this arrangement explained significantly more variance in word recognition and orthographic processing skills, as compared with the traditional arrangement.

Following this logic and using the same items and arrangement from Compton et al. (2002), our RAN letter naming (RANL) task consisted of the high-frequency lowercase letters (*a, b, d, o, p, s*), and our RAN number (RANN) task consisted of the six digits (1, 2, 4, 6, 7, 9), all presented in random order in 15 rows of five items each. Letters of the alphabet were selected to preserve the integrity of the original task and because letter names are learned and overlearned by children in Hong Kong from kindergarten onward. Any load on memory would be reduced, as the task could be done almost automatically. The alternative of substituting the familiar letters of the alphabet with Chinese characters might approximate the “alpha” aspect but run the risk of changing the structure of the tasks and of introducing the element of unfamiliarity and the need to draw on long-term memory.

The individual children were asked to read horizontally from left to right across the printed page and to name the numbers and letters as rapidly and as accurately as possible in two separate sessions of 30 s each. The total score correct within this time limit for each component was taken as the RANL or RANN score of the child. The use of scores in correctly naming the numbers or letters in unit time (30 s) made for easier administration and obviated the interpretation of negative scores if time in seconds was used as the metric. The maximum score for each part was 75, and the internal consistency Cronbach’s alpha of the two parts was .738.

*Onset–rime phonological segmentation.* The speech-sound segmentation construct for the present study was subserved by two tasks at the syllabic level: deletion of rime, and deletion of onset (see sample items in the Appendix). For deletion of rime, 10 items were spoken Chinese characters, and 10 were spoken English monosyllabic words known to the children (e.g., /m-ian/, /h-ide/). Similarly, for the onset deletion, there were 10 spoken Chinese characters and 10 spoken English words familiar to the children (e.g., /t-ian/, /g-old/). This task was first devised and used successfully by Leong and Tan (2002) in predicting Chinese word reading in two studies of Chinese children, one with 32 Grade 4 students and 38 Grade 5 students, and the other with 180 students in Grades 3, 4, and 5. The further use of the onset–rime deletion task in its present content and format to examine its role in Chinese text comprehension seemed justified. The maximum score for rime deletion and onset deletion was 20 each. Individual children listened to the spoken character or one-syllable word and were asked to delete the end sound (deletion of rime) or the beginning sound (deletion of onset) and to say what was left. Internal consistency Cronbach’s alpha for the segmentation task as a whole was .766.

## Results

### Preliminary Analyses

Table 1 displays the means and standard deviations of the various measures used in the study. The intercorrelations of these tasks after we controlled for chronological age for the total group of 518 students are shown in Table 2. As all tests were group or individually administered, there were no missing data in the data set. Preliminary scanning showed that all variables were practically normally distributed. In the structural equation analyses, the maximum likelihood fitting function was used, which was demonstrated to be quite robust to data violating normality assumptions even at small sample sizes (Hau & Marsh, 2004).

In a 3 (grade level: Grades 3, 4, 5)  $\times$  2 (gender)  $\times$  8 (text comprehension passage) multivariate analysis of variance with passage as a within-subject variable, Wilks's lambda was significant for grade,  $F(2, 517) = 11.503$ ,  $p < .001$ ,  $\eta^2 = .154$ , and gender,  $F(2, 517) = 5.047$ ,  $p < .001$ ,  $\eta^2 = .074$ . There was no Grade  $\times$  Gender interaction. Further detailed between-subjects analyses by each of the passages showed that the effect sizes for grade ranged from .064 to .217, with a mean of .104, and that the effect sizes for gender ranged from .001 to .030, with a mean of .009. Because of the very low effect sizes for gender (Cohen & Cohen, 1983), subsequent analyses concentrated on the total group of 518 students.

As discussed earlier, one important question raised recently in the reading research literature regards the passage independence of items (whether participants can answer items with above chance accuracy without reading the passages), as shown and discussed by Keenan and Betjemann (2006) and Kintsch and Kinstch (2005). To address this issue and to ensure that the specially designed Chinese text comprehension task, with its eight passages and 24 questions, was passage dependent (i.e., participants needed to read the passages to answer the questions correctly), we found that the 53 Grade 4 children not in the study who just answered the questions without reading the passages obtained a mean score of 5.377 (or 0.07 out of a maximum of 72), with a standard deviation of 2.90. The 33 university students who also just answered the questions without reading the passages obtained a mean of 25.06 (0.35 out of

a maximum of 72) and a standard deviation of 8.047. The overall performance of 0.07 by the Grade 4 students and the less than chance performance by the university students suggest that the passages needed to be read before the open-ended questions could be answered correctly. The significance of this issue is further discussed in the *Summary and Conclusion* section.

As a preliminary analysis on the appropriateness of the categorization of the tasks by their latent factor, a confirmatory factor analysis was conducted on all the tasks used in the study (see Table 3). The latent endogenous construct of text comprehension was subserved by Text Comprehension 1 and Text Comprehension 2. The latent pseudoword reading construct was subserved by PW1 and PW2. For the exogenous constructs, verbal working memory was subserved by the measurable tasks of memory span and tongue twister, RAN was subserved by RANL and RANN, and onset-rime segmentation was subserved by the deletion of rime and deletion of onset.

On the basis of the various goodness-of-fit indexes recommended by Marsh, Hau, and Grayson (2005), the fit of the model to the total group of 518 students was satisfactory,  $\chi^2(25) = 33.21$ ,  $p = .124$  (root-mean-square of approximation [RMSEA] = .025; nonnormed fit index [NNFI] = .996; comparative fit index [CFI] = .998). These fit indexes reflect the appropriateness of the tasks as measurable indicators of the various latent constructs. All the factor loadings of the tasks, with the exception of the slightly lower value for the tongue twister, were at least .70, further supporting the validity of the posited measures.

### Full Model With Structural Equation Analyses

The strength of relations among the constructs in our hypothetical model (see Figure 1) was examined with structural equation modeling using maximum likelihood estimation (LISREL Version 8.72; Jöreskog & Sörbom, 1996–2001). The model tested is summarized schematically in Figure 1. Though this model looks slightly different from that in the earlier confirmatory factor analysis, statistically they are equivalent, because the structural parts of both models were saturated with freely estimated paths linking all possible pairs of factors (MacCallum, Wegener, Uchino, & Fab-

Note. All partial correlations are significant at  $p < .001$ .

rigar, 1993). Understandably, the fit of this model (in Figure 1) was equally satisfactory,  $\chi^2(25) = 33.21$ ,  $p = .124$  (RMSEA = .025; NNFI = .996; CFI = .998). To further test whether RAN and onset-rime segmentation might have some indirect effect via pseudoword reading on text comprehension, we put both of them in the model for testing. Empirical results suggested that neither of them had such an indirect effect. When all the nonsignificant paths were removed, the fit of the model was still very good, with the major paths practically unchanged,  $\chi^2(30) = 37.48$ ,  $p = .164$  (RMSEA = .022; NNFI = .997; CFI = .998). This gives further credence to our hypothetical model as depicted in Figure 1.

Results showed that verbal working memory, RAN, and onset-rime segmentation were highly and positively correlated at around .4 to .6 (all  $ps < .01$ ; see Figure 1). However, despite their close positive relations, they had disparate effects on text comprehension and pseudoword reading. In general, with the exception of a very small positive effect ( $\beta = .11$ ,  $ns$ ) of RAN on pseudoword reading, RAN and onset-rime segmentation did not have any appreciable effect on text comprehension or pseudoword reading (all paths were nonsignificant).

Verbal working memory, however, had much stronger effects (see Figure 1). Children with better verbal working memory performed much better in pseudoword reading ( $\beta = .62$ ,  $p < .01$ ) and text comprehension ( $\beta = .83$ ,  $p < .01$ ). Though it is speculated that pseudoword reading might play the mediating role in the effect of verbal working memory on text comprehension, there is not much empirical support. If pseudoword reading had been the mediating factor, the path between pseudoword reading and text comprehension would have been much stronger (it was only .06, nonsignificant). Thus, verbal working memory helped children's text comprehension performance quite independently and directly, rather than through improving their pseudoword reading competence, at least for the tasks used in the present study.

#### *Hierarchical Regression Analyses on Text Comprehension Total Score*

Understandably, some of the tasks shared common variance in explaining children's text comprehension. To examine in greater

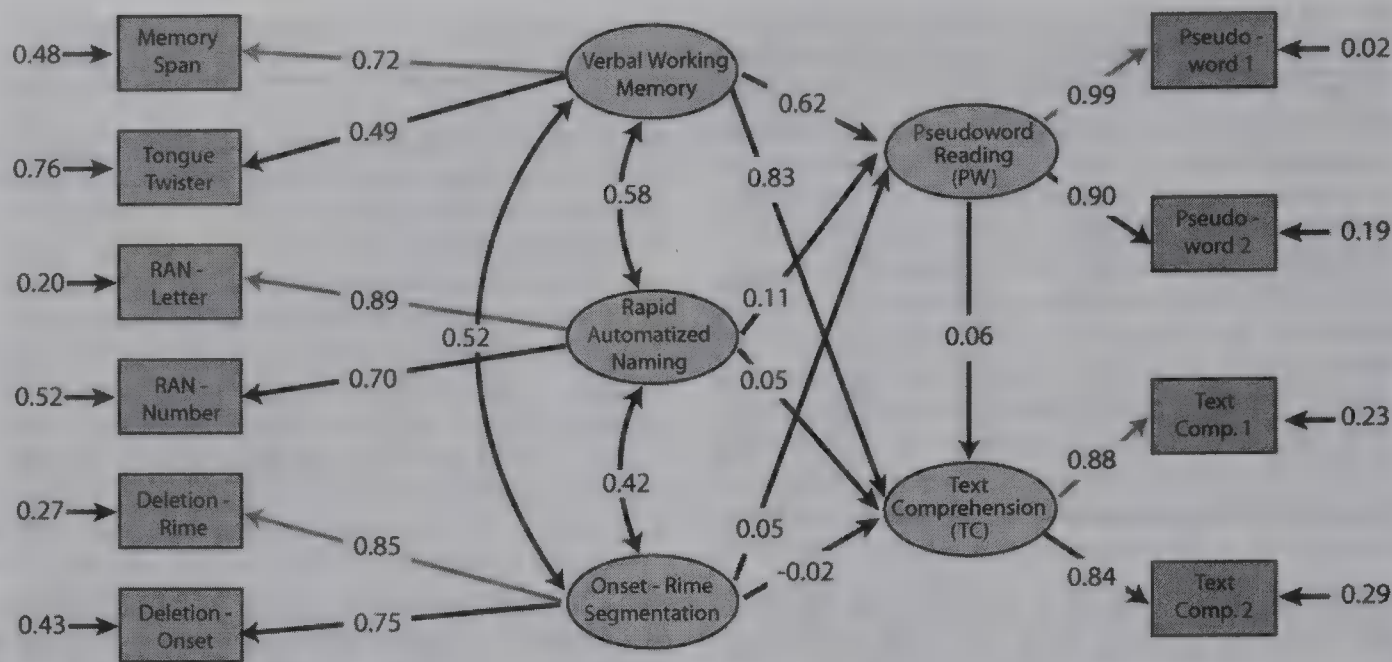

Figure 1. Structural equation modeling showing standardized effects of verbal working memory, rapid automatized naming (RAN), and onset-rime segmentation on text comprehension and pseudoword reading.  $N = 518$ ;  $\chi^2 = 33.21$ ;  $df = 23$ ;  $p = .124$ ; root-mean-square of approximation = .025.

detail the unique and common contributions of each task, we conducted hierarchical multiple regression analyses with text comprehension (sum of standardized scores of the two respective tasks) as the criterion variable. We controlled age by entering it first, while we entered the tasks in verbal working memory, pseudoword reading, RAN, and onset-rime segmentation separately (see Table 4, Models 2, 3, 4, and 5), in pairs (see Table 4, Models 6, 7, 8, 9, 10, 11, and 12), and all together (see Table 4, Model 13).

As can be seen from the analyses (see Table 4, Models 2, 6, 7, 8, 10, and 13), verbal working memory, in particular memory span ( $\beta$ s ranged from .306 to .466), substantially predicted text com-

prehension. Though these working memory tasks shared some of the variance when put jointly with other tasks, working memory's unique contributions to text comprehension remained relatively high. In comparison, PW1 also played a role in text comprehension when considered conjointly with the two working memory tasks (Model 6). It should be noted that after we adjusted for age, squared multiple correlations were .471 for the two memory tasks by themselves (Model 2), .407 for the two pseudoword tasks by themselves (Model 3), and .536 for the four tasks from the two constructs (Model 6).

In contrast, RAN and onset-rime segmentation had much smaller unique contributions in predicting text comprehension.

Table 4  
Hierarchical Multiple Regression Analyses: Predicting Chinese Text Comprehension From Verbal Working Memory, Pseudoword Reading, Rapid Automatized Naming (RAN), and Onset-Rime Segmentation

Model	Age	Predictor ( $\beta$ )								$R^2$
		Memory span	Tongue twister	Pseudoword 1	Pseudoword 2	RAN letter	RAN number	Rime deletion	Onset deletion

\*  $p < .05$ . \*\*  $p < .01$ . \*\*\*  $p < .001$ .

Standing alone (Model 4), RAN, in particular RANL ( $\beta = .315$ ), had some effect on text comprehension. However, its effect dropped moderately to .241 (Model 9) in the presence of onset-rime segmentation tasks and drastically to .157 (Model 7) in the presence of verbal working memory. This shows that the effects of RAN on text comprehension could be accounted for quite substantially by the differences in children's verbal working memory.

Similarly, though onset-rime segmentation, in particular rime deletion ( $\beta = .232$ ; Model 5), seemed to contribute to text comprehension, its effect dropped to .153 (Model 9) with RAN and to .112 (Model 8) with verbal working memory. In the last regression analysis (Model 13), in which all tasks predicted text comprehension together, it was obvious that verbal working memory had the largest unique contribution ( $\beta = .306$  for memory span;  $\beta = .148$  for tongue twister). Though the regression analysis (Model 13) suggested that one of the pseudoword reading tasks might have some unique contribution ( $\beta = .226$  for Task 1), its additional explanatory power was small (the squared multiple correlation increased from 53.6% to 55.0% in Models 6 and 13 when PW1 and PW2 were added). The details are summarized in Table 4.

In sum, the regression analyses with the total text comprehension and its component scores showed that memory span consistently had the largest effect, followed by PW1, on text comprehension. Noticeably, to a large extent, the effects of RANL and rime deletion were shared by the effects of memory span, while the effect memory was quite unique and unexplainable by the other measures. Even though pseudowords tended to have some effects on text comprehension, their additional explanatory power, beyond that of verbal working memory, RAN, and onset-rime segmentation, was relatively small in this particular study on Chinese language.

## Discussion

Inspection of the means and standard deviations of the tasks (see Table 1) shows that the text comprehension mean performance (percentage correct) was at the 53% level for the total group of 518 students, and there was the expected progression from Grades 3 through 4 to 5. One reason is that the passages were deliberately designed to be more stringent and discriminating to avoid ceiling and floor effects, which might arise with the spread of about 2 years in age. The other reason that the students could only get half of the items correct is that elementary Chinese students in Hong Kong are not well guided in their everyday learning of Chinese text materials to analyze meaning construction. They are not well taught to carry out reasoning operations, such as making assumptions, citing and validating evidence, and envisioning the writer's text world (Langer, 1986). Careful inspection of some of the written answers shows that the low-scoring ones were invariably straightforward reproductions or literal translations from the text materials, whereas the high-scoring ones took into account the structure, the gist of the essays, and the intention of the authors.

These are some examples from the written protocols of the students. In the essay on shutting the barn door after the goat had bolted (Passage 3), high scorers went beyond verbatim information to convey the idea of learning from experience, whereas low scorers simply stated the physical act of shutting the barn door. For Passage 4, "The Great Wall of China," an answer to the question

on comparing the Great Wall to a long dragon that brought out the meandering nature of the long wall in the metaphorical splendid dragon, which is also a symbol of strength and prosperity in the Chinese culture, would fetch the top credit of 3. The mere statement that the Great Wall is long and winding would fetch a score of 1. Also from Table 1, the two pseudoword reading tasks were at about a mean of 60% accuracy overall, whereas memory span was at about 49% accuracy overall. In some contrast, the phonological sensitivity tasks and RAN were generally scored higher.

Table 2 shows that the cognate tasks within each latent factor correlated highly to moderately among one another after chronological age was controlled (e.g., .889 for the two pseudoword reading tasks, .357 for the verbal working memory tasks, .607 for the two RAN tasks, and .644 for the two phonological segmentation tasks). The confirmatory factor analysis reaffirms that the indicators of verbal working memory, pseudoword reading, RAN, phonological segmentation, and text comprehension all clustered to form the components as hypothesized, with very high loadings. This lends credence to our conceptualization of the constructs as discussed earlier.

### *Contribution of Verbal Working Memory to Chinese Text Comprehension*

In the literature on reading comprehension in English, there is evidence of the important role of working memory (Cain, Oakhill, & Bryant, 2004; Cain, Oakhill, & Lemmon, 2004; Seigneuric & Ehrlich, 2005; Seigneuric et al., 2000). The storage and manipulation of linguistic materials in memory, as assessed by the kind of memory span task used, likely draw on the same or similar sorts of strategies in processing text materials and represent the resources available for text processing. There is evidence of this in the present study, and the effect of verbal working memory on text comprehension seems to apply across writing systems to both the alphabetic English and the morphosyllabic Chinese.

As shown in Table 4, as the latent constructs and tasks shared and explained jointly Chinese text comprehension, their effects varied somewhat according to what tasks were put together in the analyses. It is important to note that the verbal working memory construct uniquely contributed more to the total effects. These results are in congruence with those of the longitudinal investigation of 74 French children in Grades 1, 2, and 3 by Seigneuric and Ehrlich (2005). These researchers used a working memory task in which the children had to supply missing final words of unrelated sentences read aloud and to recall all the supplied words at the end of the set in the correct order (e.g., "1, 2, 3, 4 are digits," "A, B, C, D are letters," and "To cut meat we use a knife"). What is important is that Grade 2 working memory contributed significantly to Grade 3 reading comprehension. These authors explained that as word recognition became more automatic through the early grades, working memory became a more important determinant in reading comprehension. These results were obtained from a developmental study with 74 French children followed through Grades 1, 2, and 3; the present cross-sectional study, with a much larger number of Chinese students (518 in all), shows very similar patterns.

The structural equation modeling (see Figure 1) provides some answers to the direct and indirect effects of verbal working mem-

ory as a construct on text comprehension. The significant and high path coefficients of .83 from verbal working memory to text comprehension and of .62 from verbal working memory to pseudoword reading suggest the potent effects of the working memory construct on these two endogenous constructs. Variations in levels of the exogenous construct of working memory thus account significantly for the endogenous construct of text comprehension and also pseudoword reading. It is noteworthy that pseudoword reading does play a very small role in Chinese text comprehension (Holmbeck, 1997). It could well be that there are other constructs influencing text comprehension that were not tested here.

The better performance of the older students in inferencing might have been due to their better general knowledge, their better awareness of when and where to draw inferences, and also enhanced processing resources, such as better utilization of verbal working memory. Perusal of sample written scripts shows that students in Grade 3 and also poorer students likely gave verbatim answers taken almost directly from the text passages. They likely failed to draw analogies, such as the analogy shown in the text between the Great Wall of China and the meandering long dragon with all its splendor, prowess, and symbol of prosperity (Passage 4). These younger and poorer comprehenders might also have provided only partial answers, with little or no explanation, when multiple answers with short explanations were called for. These students also failed to grasp the symbolic values of sadness and loss conveyed by such key phrases such as "lone sail" and "distant image [of sailing boat]" in the well-known poem by Li Po, in which he bids farewell to his good friend sailing down the River Yangtze (Passage 5). These students further failed to integrate the local reference to the lowly peanut being buried in the ground and hiding its utility (Passage 6) with the more elaborate text base of being practical and unassuming. In fact, many students simply made reference from their life experience to peanuts used for making peanut butter and for other kinds of food.

### *Chinese Pseudoword Reading*

What are the plausible reasons for Chinese pseudoword reading (PW1) explaining a small amount, jointly with verbal working memory, of the variation in Chinese text comprehension (see Table 4)? At the theoretical level, the interactive constituency model of Tan and Perfetti (1998, 1999) provides the underpinning. This model posits that Chinese word identification results from the convergence of the phonological form, the orthographic form, and the semantic form, with the suggestion that phonologic-orthographic convergence is more rapid and more reliable than the orthographic-semantic. The ability to read accurately and rapidly Chinese pseudowords in the way they were designed for this study likely has some similarity to what is needed to read textual materials with understanding.

The other plausible reason is that to identify and read correctly each character constituting the two-character pseudoword, the child had to draw on his or her knowledge of the vocabulary, which has been shown to affect reading comprehension (Cain et al., 2000; Cain, Oakhill, & Bryant, 2004; Seigneuric & Ehrlich, 2005; Seigneuric et al., 2000). From observations of the performance of the students, these different strategies explained a con-

siderable number of their reading errors: reading by constituent *bujians*, using the first character to infer the second character, reading similarly configured characters, and guessing from certain constituent parts.

Our finding that pseudoword reading made a small contribution to the variation in reading comprehension of Chinese text materials may be compared with the findings regarding reading comprehension in English by Oakhill et al. (2003). These researchers found, in a two-wave study of 102 British children who were 7 to 8 years old at the first wave, a dissociation of word reading and text comprehension, even though these skills were also shown to be correlated. They found that the significant variation in comprehension was explained by tasks of text integration, metacognition monitoring, and working memory (of digits and of sentences and words). It should be noted that the researchers' inference and integration skills tasks were very short (three lines), and the children listened to this short text. In our study, the average length of the eight passages was over eight sentences, and our participants had to read each passage silently and then write their short answers to the inferential questions. Oakhill et al.'s (2003) integration of information and the story anagram tasks emphasized story structure. Our eight passages and 24 open-ended questions were much more challenging intellectually and linguistically. We probed general ideas and asked the children to hypothesize, to use schemas, to cite evidence, and generally to go beyond the information given in making inferences. The issue of the contribution of word reading (not so much vocabulary per se) to differential facets of inferential text comprehension needs further investigation.

### *Role of Phonological Segmentation and RAN*

The phonological sensitivity tasks made almost no contribution to Chinese text comprehension. This pattern likely reflects the much more predominant contributions by verbal working memory, the two-part pseudoword reading tasks, and their conjoint effect. It is also likely that phonological segmentation of onset-rime deletion plays a role only at the emergent literacy stage, as shown by Siok and Fletcher (2001) in their study of preschool and grade school Chinese children in Beijing. More important, our finding that onset-rime segmentation did not affect reading comprehension is in line with the findings with American children by Catts, Fey, Zhang, and Tomblin (1999) and with the findings by Demont and Gombert (1996) in a 4-year follow-up study of 38 French-speaking preschool children.

The low contribution by RAN (both letters and numbers) is in line with general findings from a meta-analysis by Swanson, Trainin, Necoechea, and Hammill (2003) of the correlation literature on measures of reading, RAN, phonological sensitivity, and related abilities from a large study of 2,257 American children in 49 independent samples with corrections for sample size, restriction in range, and attenuations. Swanson et al. found that correlations between RAN and phonological sensitivity were low (.38), and RAN and phonological sensitivity tasks correlated moderately with real word reading (.46 and .48, respectively). RAN and phonological sensitivity were found to be less important than measures of spelling and word attack skills and also played a less important role in reading comprehension. It thus appears that even with quite disparate writing systems—English and Chinese—there

are common and general findings on the role of RAN in reading, if one does not go into the intricacies of different formats of RAN, theoretical underpinnings, and practical applications. In the present study, the two tasks used (RANL and RANN) were easy, were quick to administer (30 s per task per child), and had a role, albeit a small one, in explaining Chinese reading comprehension.

### Summary and Conclusion

To the best of our knowledge, our study with a large sample of 518 Chinese children might be among the first to investigate these children's text comprehension and the relative contribution of some cognitive and linguistic skills. We acknowledge some shortcomings in the study. First, the study was confined to Cantonese-speaking Chinese children in Hong Kong between the ages of 9 and 11 years in Grades 3, 4, and 5 and was not able to assess the developmental paths and possible changes in the children's performance of the different tasks and their interaction. Second, the text-inferencing passages were relatively short, even though the open-ended written answer format was easy to use and showed reasonable content validity. Third, as working memory is a system comprising separable components, multiple tasks and assessments over time are needed to examine alternative theoretical accounts of working memory capacity (Alloway, Pickering, & Gathercole, 2006). Fourth, structural equation modeling, with its composite measurement model and path model (see Figure 1), describes relations of dependency among the latent constructs, and no claim is made to causality. The structural equation model with its acceptable "good" fit and the prediction of Chinese text reading from the different equations of the hierarchical multiple regression analyses (see Table 4) are attempts at answering some research questions and should be interpreted as approximations of reality.

We would, however, also like to suggest that the present study contributes to our knowledge of text comprehension in Chinese in several ways. First, it shows that carefully constructed and relatively short text passages with well-designed, open-ended, inferential questions can tap text comprehension with high fidelity. The related use of the written protocols combining reading and writing was effective in studying text comprehension (see Kintsch & Kintsch, 2005; Swanson & Berninger, 1996). The open-ended inferential questions requiring short written answers showed the passage-dependent nature of the task (Keenan & Betjemann, 2006), as attested by the virtual failure of the random group of 53 Grade 4 students scoring at 7% by just answering the questions. Second, text comprehension has many facets, as shown by our careful study of the written protocols of the students. Third, two-character Chinese pseudowords contributed in some way to reading comprehension, especially in lower elementary grades, thus showing the role of knowing characters and words analytically and synthetically. Fourth, in support of the literature on English reading comprehension, verbal working memory had a strong effect on Chinese text comprehension and, in fact, had the largest joint or unique effects on overall text comprehension. Fifth, again in common with findings from English, there were small, though statistically significant, contributions by rapid naming of letters to the Chinese text comprehension. The challenge is to specify with fine-grained analyses how these various components might relate to different facets of reading comprehension in Chi-

nese and to understand more fully the process of inferencing in text materials as a whole at different elementary grade levels. Moreover, general language mechanisms underlying poor reading comprehension (Nation et al., 1999; Perfetti et al., 2005; Stothard & Hulme, 1992) should be further investigated.

## 1 閱讀理解 (Text comprehension No. 2 "Spear and Shield")

發明家手持矛和盾，與朋友比賽。

對方的矛如雨點般向他刺來，發明家用盾左抵右擋，還是難以招架。在這緊張危急的關頭，發明家忽然產生了一個想法：「盾太小了！如果盾大得像鐵屋子，我鑽在鐵屋子裏，敵人就一槍也戳不到我了！」

可是，這樣固然安全，自己卻變成了只能縮在殼裏保命的蝸牛或烏龜。

對了，在鐵屋子上開個小洞，從洞裏伸出「矛」——

槍口或砲口。當然，這鐵屋子還要會跑，得裝上輪子，安上履帶。於是，發明家發明了坦克。

The inventor was holding a spear and a shield and was jousting with his friend.

His opponent was using his spear to hit at him like raindrops. Even though the inventor was using his shield left and right to ward off the attack, he still found it difficult to defend himself. During this critical moment, the inventor had a thought: "The shield is too small! If it were like a big house made of iron, I can hide inside this iron house and the enemy cannot spear me!"

However, while the iron house might protect him from the spear attack he would be like a snail or a tortoise hiding in its shell just to be safe.

He had the bright idea of opening a small hole in the iron house and of showing only his "spear"—a gun or cannon. Of course, this iron house will need to be able to move fast on wheels with traction tires. Thus was born the idea of the prototype modern attack tanks.

## 1a 矛和盾分別有什麼作用？

What are the different uses [functions] of the spear and the shield?

## 1b 請說明坦克成為強大的武器的原因。

Please explain why the tank is a powerful weapon.

## 1c 請給這篇短文加上合適的標題，並解釋你的理由。

Please give the short passage a title, and explain your reasons.

## 2 假詞 (Pseudoword)

炮喻[pau3 jy6]

橫蘊[wan4 wan3]

潭砌[tam4 tsai3]

■遮[luŋ1 dze1]

僂瀑[wui1 buk6/bou6]

塌減[tap3 gaam2]

盞錦[dzan2 gam2]

遂促[sœy6 gwat9]

鋒棕[fun1 dzun1]

疼撤[tan4 tsit8]

## 3 「語文工作記憶」項目 Memory Span Task (MEMSP)

園子四面有高圍牆。 The courtyard has on four sides a high wall.

用顯微鏡才能看到細胞。 A microscope can show minute cells.

海底蘊藏著豐富的石油。 In the seabed can be found rich reserves of oil.

問題：顯微鏡有甚麼作用？ Question: What does a microscope do?

答案：放大（物體的影像） Answer: Amplify or magnify (images of objects).

詞語：圍牆、細胞、石油 Last word of each sentence: wall, cells, oil

## 4 急口令 (tongue-twister)

1. 東門南門 [dung1 mun4 naam4 mun4] East gate south gate

東門東家 [dung1 mun4 dung1 gaa1], East gate east (also host house),

南門董家 [naam4 mun4 dung2 gaa1]. South gate Tung house.

東董兩家 [dung1 dung2 loeng5 gaa1], East Tung [play on speech sound with mainly tones 1 and 2] two house(s).

同種冬瓜 [tung4 zung3 dung1 gwaal]. Together planting melon(s).

# Development of Word Reading Fluency and Spelling in a Consistent Orthography: An 8-Year Follow-Up

Karin Landerl

University of Tuebingen and University of Salzburg

Heinz Wimmer

University of Salzburg

In a longitudinal study, development of word reading fluency and spelling were followed for almost 8 years. In a group of 115 students (65 girls, 50 boys) acquiring the phonologically transparent German orthography, prediction measures (letter knowledge, phonological short-term memory, phonological awareness, rapid automatized naming, and nonverbal IQ) were assessed at the beginning of Grade 1; reading fluency and spelling were tested at the end of Grade 1 as well as in Grades 4 and 8. Reading accuracy was close to ceiling in all reading assessments, such that reading fluency was not heavily influenced by differences in reading accuracy. High stability was observed for word reading fluency development. Of the dysfluent readers in Grade 1, 70% were still poor readers in Grade 8. For spelling, children who at the end of Grade 1 still had problems translating spoken words into phonologically plausible letter sequences developed problems with orthographic spelling later on. The strongest specific predictors were rapid automatized naming for reading fluency and phonological awareness for spelling. Word recognition speed was a relevant and highly stable indicator of reading skills and the only indicator that discriminated reading skill levels in consistent orthographies. Its long-term development was more strongly influenced by early naming speed than by phonological awareness.

**Keywords:** reading fluency, spelling, longitudinal assessment, long-term prediction of reading and spelling

Only recently, word reading fluency has moved from being a neglected aspect of reading to being a popular topic in the field of reading research. As Ehri (2002) stated,

One of the great mysteries to challenge researchers is how people learn to read and comprehend text rapidly and with ease. . . . A large part of the explanation lies in how they learn to read individual words. Skilled readers are able to look at thousands of words and immediately recognize their meanings without any effort. (p. 7)

A longitudinal study with a sample of normally developing readers of German allowed us to follow the development of word reading fluency and also orthographic spelling skills over almost 8 years, from school entry through to Grade 8.

Most longitudinal studies with English-speaking children did not even include measures of reading fluency but reported devel-

opment in word reading accuracy only (see Parrila, Aunola, Leskinen, Nurmi, & Kirby, 2005, for a review). In phonologically more transparent orthographies, however, word reading accuracy is often close to or at ceiling after only a few months of formal reading instruction (Cossu, Giuliotta, & Marshall, 1995; Oney & Goldman, 1984; Wimmer & Hummer, 1990), and word reading speed is the only word reading measure that differentiates between good and poor readers in higher grades.

There exist a few studies reporting longitudinal development of reading fluency in orthographies with consistent grapheme–phoneme correspondences. Bast and Reitsma (1998) followed the reading development of 235 Dutch children from kindergarten to the end of Grade 3. The first assessment of word reading fluency was carried out 3 months after the onset of formal reading instruction, with two further assessments during first grade, two assessments in second grade, and a final assessment toward the end of third grade. At each of the measurement points, children were given word lists, and the dependent variable was the number of words read correctly within a certain time limit (between 1 and 3 min). Unfortunately, Bast and Reitsma did not report reading accuracy separately from reading speed. Only for the later measurement points is it likely that accuracy among these readers of the consistent orthography of Dutch was high so that the reported measure can be interpreted as a pure measure of reading fluency. The finding of importance is that, with respect to reading fluency, the rank ordering of individuals was highly stable for the measurements after Grade 1, and individual differences in word recognition fluency even increased over time.

Parrila et al. (2005) recently reported a longitudinal assessment of a sample of 197 Finnish children's development of oral reading fluency (reading a short text as quickly as possible) from the

beginning of Grade 1 until the end of Grade 2. This study also indicated high stability of reading fluency over four measurement points (two per school year), but, in contrast to Bast and Reitsma (1998), the authors did not find evidence that individual differences increased during the project period. Once again, it is problematic that Parrila et al. (2005) did not report reading accuracy separately from reading fluency, so that it is unclear whether these two measures were confounded. Parrila et al. (2005) also reported high stability in reading development for a sample of 198 Canadian children who were followed from Grade 1 up to Grade 5. However, this finding is not informative with respect to reading fluency development as—quite typical for studies with English-speaking children—the dependent measures only included measures of word reading accuracy but no measure of reading speed.

De Jong and van der Leij (2002) followed the reading fluency development of 141 Dutch children. They reported a correlation of .69 between word reading fluency (number of words read correctly in 1 min) at the end of Grade 1 and Grade 3, suggesting a high stability over the years. When the students were in Grade 6, de Jong and van der Leij (2003) retested specifically selected subgroups from their longitudinal sample. A group of dyslexic children was selected on the basis of their reading skills in Grade 3, when their level of word reading fluency was, on average, more than two standard deviations below the age norms. This strong deviation from the mean was still evident in Grade 6, confirming the high stability of word reading fluency. It is interesting that at the end of Grade 1, dyslexic children's word reading accuracy was high and not significantly different from that of a control group of children with age-adequate reading development. This finding indicates that the extremely low reading fluency that these children exhibited was not caused by lack of knowledge of the graphophonic connections.

In an Austrian longitudinal study Klicpera and Schabmann (1993) documented 356 German-speaking children's reading development from Grade 2 to Grade 8. In the middle of Grade 2, children were assigned to five reading level groups on the basis of their reading fluency. The stability for the highest and lowest reading level groups in particular was very high. Only 2 children who were among the 5% of poorest readers in Grade 2 developed average reading skills in Grade 8, but 94% of this group still performed below Percentile 15. The children who had been assigned to the lowest reading level in Grade 2 exhibited a reading fluency in Grade 8 that was comparable to that of average readers in Grade 2. Thus, their reading speed development was about 6 years delayed. Nevertheless, word reading accuracy was high even among the poorest reading level group. Already in Grade 2 they read fewer than 20% of the presented words incorrectly. This is impressive, given the fact that reading was assessed under speed instruction. Without the emphasis on reading as fast as possible, accuracy might have been even higher. Obviously, there was not much room for further improvement in reading accuracy later on. In Grade 8, even the poor readers made errors on fewer than 10% of the presented words.

The current study followed children's literacy development over an even longer time period than any of the studies reported above, namely from school entry until the middle of Grade 8. This longitudinal assessment allowed us to test the stability of reading fluency development and also of orthographic spelling skills over three assessments (end of Grade 1, beginning of Grade 4, and

middle of Grade 8). Furthermore, the design of the study also enabled us to assess the predictive power of standard psycholinguistic measures for the longitudinal development of reading fluency and spelling. The first assessment was carried out at the beginning of Grade 1, before the onset of formal reading instruction, and included measures of phonological processing (phonological awareness, phonological short-term memory), letter knowledge, and rapid automatized naming. It is important to note that the German/Austrian kindergarten system does not provide explicit reading preparation. During their preschool years, children are supposed to develop in the context of playing. Reading, spelling, and arithmetic are only introduced in first grade. This difference between the German and the Anglo-American preschool education systems became clearly evident in a direct comparison of the letter knowledge and phonological awareness of Austrian and U.S. kindergartners carried out by Mann and Wimmer (2002). Percentages of correctly named letters were above 90% for U.S. kindergartners but only around 30% for their Austrian age mates.

Findings of earlier phases of this longitudinal assessment were reported in Wimmer, Mayringer, and Landerl (2000, Study 2) and Wimmer and Mayringer (2002, Study 2). The main findings were that serious deficits in reading fluency and orthographic spelling were not strongly associated with each other and that they might have been based on different cognitive deficits. In Wimmer et al. (2000), we reported that those children who entered school with serious deficits in phonological awareness later on developed problems in orthographic spelling and irregular word reading but not in the domain of phonological decoding (i.e., nonword reading). Obviously, this is in striking contrast to findings with English-speaking children, for whom deficits in phonological awareness have been demonstrated to be closely associated with problems in phonological decoding (Vellutino, Fletcher, Snowling, & Scanlon, 2004) and for whom phonological decoding, in turn, is seen as a bottleneck to further reading acquisition (Perfetti, 1985). The combination of the highly consistent grapheme-phoneme correspondences of German orthography and a systematic phonics teaching approach seems to enable even children who enter school with low phonological skills to master the initial hurdle of phonological decoding. Only when the relationships between spoken and written language become more complex, as in irregular word reading or spelling, where German orthography is clearly less consistent than in the reading direction, do early phonological deficits seem to have a more persistent negative influence on children's literacy development.

While early phonological awareness deficits did not have a strong influence on children's later reading development, deficits in sequential naming speed, measured by a rapid automatized naming paradigm, did: Children who entered school with a serious naming speed deficit turned out to read both words and nonwords with strikingly low reading fluency in Grade 4. In addition, they showed problems in orthographic spelling.

In a second, retrospective analysis of the longitudinal data, Wimmer and Mayringer (2002) selected three deficit groups from the large normative sample of 301 children on the basis of their reading and spelling performance in Grade 4: A group of dysfluent readers who had age-adequate skills in orthographic spelling, a group of poor spellers with age-adequate reading fluency, and a group of students who were deficient in both reading fluency and orthographic spelling. It turned out that the dysfluent readers

already showed marked problems in rapid automatized naming of objects at school entry. The poor spellers, conversely, typically started into their school career with a deficit in phonological awareness. The group with combined reading and spelling deficits showed problems in both cognitive domains when they entered school.

In summary, the findings suggest that, at least in the German context of a consistent orthography and a synthetic phonics teaching approach, reading development depends more strongly on adequate naming speed than on phonological awareness. Similar findings come from studies in Dutch (de Jong & van der Leij, 1999, 2002) and Italian (Di Filippo et al., 2005). This is plausible, as the main problem of poor readers in phonologically transparent orthographies is extremely low reading fluency, while reading accuracy is usually high (de Jong & van der Leij, 1999; Landerl, Wimmer, & Frith, 1997; Wimmer, 1993; Zoccolotti et al., 2005). The literacy skill that does depend on good phonological awareness is spelling rather than reading. However, note that it is not the component of phoneme segmentation in spelling that is predicted by phonological awareness. After only few months of formal instruction, German-speaking children are usually very well able to translate even complex phoneme sequences into phonologically plausible grapheme sequences (Wimmer & Landerl, 1997). However, such a systematic phoneme–grapheme translation is not sufficient to spell words orthographically correctly, because the consistency of phoneme–grapheme correspondences is much lower than the consistency of grapheme–phoneme correspondences. Quite often, there are two or three different possibilities to translate a certain phoneme into a phonologically adequate grapheme, but obviously only one of these possibilities is orthographically correct. A plausible explanation for why phonological awareness might be relevant for orthographic spelling is that the build-up of stable representations in orthographic memory requires phonological underpinning—that is, multiple and redundant associations between the letters and sounds of specific words (Ehri, 1992; Perfetti, 1992). Deficits in phonological awareness might be an indicator that phonological representations are not well enough specified to be accessible for the formation of such associations (Snowling, 2000).

Two main questions are addressed on the basis of the Grade 8 assessment: First, how stable was the development of reading fluency and orthographic spelling over the 8 years of the reported longitudinal study? The second question we want to address is to what extent the pattern of predictions reported for Grade 4 can be replicated in Grade 8. Predictor measures assessed at the beginning of Grade 1 were tests of letter knowledge, rapid automatized naming, phonological processing (awareness and short-term memory), and nonverbal IQ.

After Grade 4, all children change to different secondary schools in the Austrian school system, which made it impossible to keep track of all participants of the originally large sample of 356 children. Still, we did not want to miss the unique opportunity to get longitudinal information on children's literacy development by collecting data from as many children as possible before some of them left school after the 9 years of obligatory schooling in the Austrian school system.

## Method

### *Sample and Procedures*

In Grade 1, a large sample of 356 children, from eight schools and 23 classrooms, was tested. In Grade 4, 296 children of the original sample could be retested; 60 children had moved or were not in school on the day of testing. Almost 8 years after the first assessment, we tried to contact all students who had participated in Grade 4. For 83 students, no addresses were available, so that they could not be invited to participate. From those who received our letter of invitation to participate in a further assessment at the Department of Psychology, 98 did not respond or declined. The number of students who agreed to participate was 115 (65 girls and 50 boys). All students attended Grade 8. Mean ages at the various assessment points were 6.9 years at the beginning of Grade 1, 7.5 years at the end of Grade 1, 10.2 years in Grade 4, and 14.3 years in Grade 8 ( $SD = 0.5$  years at all assessment points). Only data from children who participated in all assessments are reported in this article.

In the first 2 months after children entered school, we assessed phonological processing (awareness and short-term memory) and rapid automatized naming. Nonverbal IQ was measured in the second test session at the end of Grade 1. Reading and spelling skills were assessed at the end of Grade 1, beginning of Grade 4, and middle of Grade 8. All first-grade and fourth-grade assessments were carried out in the school; only the last assessment in Grade 8 took place in our lab. Apart from the spelling tests in Grade 4 and Grade 8, which were administered groupwise, all testing was done individually. Individual testing was carried out in a separate room and lasted between 30 and 40 min at each measurement point. All testing was carried out by trained master's and doctoral students.

### *Measures*

#### *Beginning of Grade 1*

**Letter knowledge.** Children were presented with the most frequent 19 uppercase letters and were asked to name them. Either letter name or letter sound counted as a correct response.

**Rapid automatized naming.** Four object pictures (car, ball, dog, mouse) were introduced, and the child was asked to name them as rapidly as possible. A further practice trial with two lines of these pictures familiarized children with the demands of rapid naming. The test page consisted of eight lines, with 4 pictures on each line (total of 32 pictures), with the pictures in varying order in each line. After the first four lines, the experimenter recorded the response time without interrupting the child. At the end of the eight lines, response time was recorded again. The correlation between the first and second halves of the naming speed task was .61.

**Phonological short-term memory.** Children were asked to repeat 16 sets of (C)CVC nonsense syllables. Eight items consisted of two syllables (e.g., *tes-bof*), the next eight syllables consisted of three syllables (e.g., *gat-fos-hap*). The correlation between two- and three-syllabic items was  $r(295) = .48, p < .001$ .

**Phonological awareness.** Manipulations on the phoneme level are usually rather difficult for Austrian 6-year-olds, who receive no reading preparation in kindergarten. In earlier studies, we found

floor effects for traditional phoneme awareness tasks such as phoneme deletion or phoneme substitution (Mann & Wimmer, 2002; Wimmer, Landerl, Linortner, & Hummer, 1991). To design a task with an acceptable level of difficulty, we developed a paradigm in which children had to imitate a phoneme segmentation modeled by the experimenter. The experimenter explained that words can be divided into smaller parts and demonstrated this with *fee*: /f/-/e:/. Children were instructed to imitate the segmentation procedure modeled by the experimenter. After the child had repeated the practice item correctly, the experimenter presented six CV words and six CVC words. For each item, the experimenter said first the word and then the constituent phonemes, and children had to imitate her by producing both the word and the segmented sounds. The idea was that a child who did not understand the relation between the word and its segments would find the task difficult, while awareness of the sound structure of words would make it easier to imitate the experimenter correctly. This measure bears similarity with the phonological memory task, in which nonsense syllables instead of phoneme sounds had to be repeated. However, the correlation between the phoneme task and the nonsense syllable task was only moderate (.30,  $p = .001$ ), so that only 9% of the variance of our phonological awareness measure could be explained by phonological memory capacity. The clearly higher correlation with letter knowledge (.57,  $p < .001$ ) suggests that children profited from knowledge of letter-sound associations. The correlation between letter knowledge and phonological memory was also only moderate (.20,  $p < .05$ ), indicating that children's letter knowledge was not only based on rote memory of the letter names. The reliability of the task was satisfactory. The correlation between CV and CVC items was .58 ( $p < .001$ ). For a subsample of 40 randomly selected children, we carried out an item-based analysis. Internal consistency turned out to be high ( $\alpha = .80$ ).

### End of Grade 1

**Nonverbal intelligence.** To assess children's nonverbal cognitive skills, we gave them Raven's Coloured Progressive Matrices (Schmidtke, Schaller, & Becker, 1978).

**Reading fluency.** Children were given two word and two nonword lists. One word list consisted of 9 one- and two-syllabic high-frequency concrete nouns; the other one consisted of 9 one-syllabic high-frequency function words. The task was introduced by a practice sheet with six words. One of the nonword lists consisted of 9 two-syllabic nonwords without consonant clusters; the other list included 9 one-syllabic nonwords with consonant clusters in onset and/or coda position. The nonword reading paradigm was also introduced by a practice list consisting of six nonwords. Children were instructed to read "as quickly as possible, without making mistakes." Both number of reading errors and reading time for each list were recorded: Reliability of the fluency tasks (syllables per minute) is evident from the high correlations among the four measures (ranging from .83 to .92,  $ps < .001$ ).

**Spelling.** Eleven high-frequency words were dictated to each child individually. After only 8 months of formal instruction, it did not seem appropriate to expect children to spell the words orthographically correctly. We rather wanted to know how well children would be able to translate the phoneme code into a phonologically plausible letter sequence. Thus, we scored whether a spelling was phonologically adequate in the sense that each sound in the word pronunciation was translated by an acceptable grapheme. To make

phoneme segmentation more difficult, we ensured that each of the words included a consonant cluster in the word onset position, and three words included a second consonant cluster in the word-final position.

### Grade 4

**Reading fluency.** Children were asked to read aloud a short story and two word lists from a standardized reading test battery (Landerl, Wimmer, & Moser, 1997). The text consisted of 57 words and was of simple content, so that reading time would not be affected by comprehension difficulties. The word lists each consisted of 11 complex compound words typical for German language (e.g., *Fruchtsaft*—fruit juice, *Geburtstagskuchen*—birthday cake). Children were instructed to read "as quickly as possible, without making mistakes." The correlation between reading fluency for the short text and the compound word lists was .88 ( $p < .001$ ). The test handbook reports satisfactory reliability (parallel test method) for both compound words (.93) and text (.90).

**Spelling.** Children had to fill 35 dictated words into sentence frames clarifying the word meaning. The words were specifically selected so that a simple phoneme-grapheme translation would not be sufficient to spell the words orthographically correctly. Each word included at least one orthographic marker typical for German orthography. The full sentence was read out by the experimenter, then the word to be spelled was repeated. Finally, the full sentence was repeated once more. Half of the sentences were taken from a standardized spelling test (Landerl, Wimmer, & Moser, 1997) with adequate reliability (.74); no reliability data were available for the current sample.

### Grade 8

**Reading fluency.** Reading fluency was assessed with two text reading paradigms. All texts were short and simple, so that good comprehension was ensured. The main criterion was the speed with which the texts could be read. First, participants were asked to read two short texts out loud. Text 1 was about the development of the Internet and consisted of 73 words and 177 syllables. Text 2 was about a new electric fence for cattle and consisted of 92 words and 156 syllables. Both errors and reading times were recorded. The correlation for reading time for the two texts was .85 ( $p < .001$ ). Asking participants to read aloud is an efficient way to assess both reading accuracy and reading speed; however, reading aloud is a rather untypical reading activity for older readers. The more natural reading activity is silent reading, which was also assessed. Three different texts, consisting of 260 words and 536 syllables altogether, were presented on a computer screen. To cover the probably widespread interests of our participants, we ensured that the texts were about very different topics (the Chinese Wall, legal restrictions for selling certain alcoholic drinks to adolescents, and an incident in which a hawk attacked a dog). Two texts were selected from daily newspapers, and one text came from a science book for adolescents. Participants were asked to read each text silently as quickly as possible and to press the space bar, triggering the response time measurement, when finished. The procedure was introduced by a short practice text consisting of 57 words. To ensure that participants read the texts carefully, the experimenter asked a short question after each text. Although they

had not been informed about the comprehension questions before reading the text, all participants answered these questions correctly. These correct answers show that participants attended to the text and that the texts were of a rather simple comprehension level for that age group. It is therefore unlikely that reading fluency was strongly influenced by comprehension difficulties. Obviously, word reading accuracy could not be measured for this paradigm; only reading time was recorded. Correlations between the texts ranged from .88 to .91 ( $ps < .001$ ).

*Spelling.* A standardized classroom test (Kersting & Althoff, 2004) was given in which students had to supply 68 dictated words or phrases to a cloze text. Each sentence was read out loud by the experimenter, and the word to be spelled was repeated. The test handbook reports high internal consistency (Cronbach's  $\alpha = .93$ ).

Results

Attrition

Table 1 presents the means and standard deviations for the prediction measures separately for those 115 children who still participated in the study in Grade 8 and those 241 children who declined to participate in Grade 8. For letter knowledge, rapid automatized naming, phonological short-term memory, and nonverbal IQ, no statistical differences were found. On the phonological awareness measure, those children who dropped out of the study later on performed significantly lower than those who still participated in Grade 8,  $t(352) = 2.68, p = .008$ . Note, however, that the difference between the two groups was only 9%, which is small in relation to the standard deviation of 29%. We also compared Grade 4 performance for those 115 children who participated in all assessments and those 180 children who still participated in Grade 4 but not later on: No difference was found for word reading fluency (Grade 8 participants:  $M = 174$  syllables/min,  $SD = 47$ ; Grade 8 nonparticipants:  $M = 164$  syllables/min,  $SD = 47$ ),  $t(293) = 1.76, ns$ . Only with respect to spelling was there a rather small but, because of the large sample size, nevertheless significant difference: Children who dropped out of the study later on spelled 71% of the dictated words correctly, while those who participated in Grade 8 produced 75% correct spellings,  $t(293) = 2.1, p = .04$ .

Table 1  
*Descriptive Statistics of Prediction Measures for Children Who Participated in Grade 8 and Those Who Dropped Out of the Study*

Prediction measure	Participants ( <i>n</i> = 115)		Nonparticipants ( <i>n</i> = 241)	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Letter knowledge (% correct)	60.4	30.7	54.6	27.9
Phonological awareness (% correct)	60.5	28.5	51.6	29.4
Phonological short-term memory (% correct)	56.7	29.7	55.7	30.0
RAN (words/min)	56.1	12.1	54.8	11.1
Nonverbal IQ	117.0	12.5	115.5	12.4

Note. RAN = rapid automatized naming.

Development of Reading Accuracy

The upper section of Table 2 presents the accuracy measures for reading for the end of Grade 1, Grade 4, and Grade 8. It is evident that after only 1 year of formal reading instruction, children showed high accuracy for both words and nonwords. Actually, 51% and 33% of the children read the word and nonword lists without errors. Only 4 children (4% of the sample) read fewer than 80% of the words correctly, and only 12 children (10%) read fewer than 80% of the nonwords correctly. The minimum accuracy scores of 72% and 61% correct indicate that none of the young readers showed serious problems with phonological decoding. Although individual children certainly still needed more practice, all children showed good competence in translating grapheme sequences into word or nonword pronunciations; thus, they had good knowledge of the alphabetic mapping system. For the interpretation of all accuracy scores presented in Table 2, it must be noted that all reading tasks were given under time pressure. Children were instructed to “read as fast as you can, without making mistakes.” It can be assumed that accuracy scores would be even higher if the instruction had been to read as carefully as possible.

Development of Reading Fluency

For each grade level, we computed scores of number of syllables read per minute. Because reading accuracy was high in all assessments, it was not necessary to correct the reading fluency scores for number of errors, and the scores were not confounded with reading accuracy. In Grade 1, separate scores were computed for the two word reading lists and the two nonword reading lists. In Grade 4, the short text and the two word lists were combined for this measure. In Grade 8, separate scores were computed for reading aloud and reading silently. The descriptive statistics for these combined fluency measures are presented in the middle section of Table 2. It is not surprising that reading fluency increased dramatically over the 8 years of the study. In Grade 1, there was a very high correlation ( $r = .91, p < .001$ ) between reading fluency for words and nonwords, indicating that children were using a strategy of phonological decoding for words as well as nonwords. However, Table 2 shows that, even at that early point in reading development, children were clearly better at reading words compared to nonwords,  $t(114) = 14.9, p < .001$ . Another important observation is the enormous variability of the fluency measures that was evident in all grade levels. In Grade 8, silent reading was clearly faster than reading aloud. The correlation between reading aloud and silent reading was substantial ( $r = .71, p < .001$ ).

Development of Spelling Skills

The important finding here is that after only 1 year of formal instruction, children were highly accurate in translating word pronunciations into grapheme sequences. The lower section of Table 2 shows that in Grade 4 children spelled a larger percentage of the dictated words correctly than in Grade 8. This was due to the higher degree of difficulty of the word material used in the Grade 8 test. Kolmogorov–Smirnov tests showed that scores on both the Grade 4 and the Grade 8 spelling measures were normally distributed ( $Zs = 1.1$  and  $0.9$ , respectively,  $ps > .1$ ). The Grade 8 measure was a standardized spelling test, which allowed us to

Table 2  
Descriptive Statistics of Reading and Spelling Measures in  
Grades 1, 4, and 8

Measure	M	SD	Min	Max
Reading accuracy (% correct)				
End of Grade 1

compare our sample with the norming sample. The mean performance of the current sample corresponded to the 54th percentile.

### Stability of Reading Fluency and Spelling From Grade 1 to Grade 8

The second and third sections of Table 3 inform on the stability of the differences in reading fluency and spelling. In spite of the long time periods between the assessments, high correlations could be

observed for word reading fluency. Even the correlations between reading fluency in Grade 1 and Grade 8, with an interval of almost 7 years, were around .60. The correlations for reading aloud and reading silently in Grade 8 were almost identical. The correlation between phonological spelling in Grade 1 and orthographic spelling in Grade 1 was also substantial and close to .50. The correlation between orthographic spelling in Grade 4 and Grade 8 was once again high.

Figure 1 examines the stability of reading fluency in more detail by plotting word reading fluency in Grade 1 against word reading fluency (for reading aloud) in Grade 8. Almost all of the 11 children who performed more than one standard deviation below the group mean in Grade 1 were still more than one standard deviation below the mean in Grade 8, which indicates high stability for deficits in reading fluency. Only 1 of the group of novice poor readers showed a Grade 8 reading fluency score that was actually slightly above average; 2 further students moved to the low average range. However, children who were already reading fluently in Grade 1 (more than one standard deviation above the group mean) without exception developed at least average reading skills later on. Thus, they had a very low risk of developing reading problems over the following years. The same scatterplot was also inspected for silent reading in Grade 8, and the findings were highly similar. We also inspected the scatterplots for reading fluency in Grades 1 and 4 and in Grades 4 and 8, and the stability was similarly high.

In an analogous scatterplot, we inspected whether early phonological spelling—that is, systematic phoneme-grapheme translation—is a precursor of later orthographic spelling skills. In Figure 2, phonological spelling skills in Grade 1 are plotted against orthographic spelling skills in Grade 8. In the phonological spelling task in Grade 1, 68 children—that is, almost 70% of the sample—performed at ceiling (no spelling errors or one error). The interesting finding here is that most of the 15 children who had problems with phonological spelling at the end of Grade 1 and performed more than one standard deviation below the group mean developed below average orthographic spelling skills later on. Only 3 of these students showed orthographic spelling skills in the low average range in Grade 8.

### *Prediction of Reading Fluency and Orthographic Spelling*

The first section of Table 2 presents the correlations among the prediction measures and between these measures and the later reading fluency and spelling measures. Of interest is that nonverbal IQ was not associated with any of the other prediction measures but showed low but significant associations with reading fluency (not Grade 1) and also with all spelling measures. As already mentioned, early letter knowledge was substantially associated with phonological awareness and also with all other verbal predictor measures. Both letter knowledge and phonological awareness were associated with all reading fluency and spelling measures, and this was also the case for the rapid automatized naming measure. It is interesting that the phonological short-term memory measure was not associated with any of the reading fluency and spelling measures except for spelling in Grade 8.

To determine the specific contribution of rapid automatized naming and phonological processing (awareness and short-term memory) for the later literacy skills, we conducted two hierarchical linear regression analyses involving three steps each for each measure of reading fluency (Grades 1, 4, and 8) and orthographic spelling (Grades 4 and 8). Phonological spelling at the end of Grade 1 was not considered as a dependent measure because of the obvious ceiling effect in children's performance. In both analyses,

nonverbal IQ and letter knowledge entered the regression equation in the first step. Rapid automatized naming and phonological processing (awareness and short-term memory) entered the equation in either the second or the third step: In one of the analyses, rapid automatized naming entered the equation in the second step and phonological processing (awareness and short-term memory) entered in the third; the order of steps was reversed for the other analysis. Phonological awareness and phonological short-term memory were entered together, as our phonological awareness measure was obviously influenced by phonological memory. With these regression analyses, we hoped to determine whether each one of the predictor skills contributed variance to performance on the dependent measure that was not already accounted for by the other.

As can be seen from Tables 4 and 5, rapid automatized naming contributed independent variance to reading fluency in all grade levels. The phonological measures contributed significantly to word reading fluency in Grade 1 only, as well as to the spelling measures in Grades 4 and 8, but they were no longer predictive for the later assessments of reading fluency in Grades 4 and 8. In summary, these regression analyses indicate that the phonological measures (phonological awareness and phonological short-term memory) accounted for significant variance for early reading fluency (Grade 1) as well as for orthographic spelling, even if the

Figure 2. Scatterplot for phonological spelling in Grade 1 and orthographic spelling in Grade 8 (full reference lines represent the mean scores; dotted reference lines represent  $\pm 1$  SD).

variance contributed by rapid automatized naming was already accounted for. Early rapid automatized naming, conversely, was a significant and consistent predictor of reading fluency at all measurement points.

### Discussion

In line with earlier studies on the longitudinal development of reading fluency in consistent orthographies, we found a very high stability of reading fluency development over almost 8 years. This stability was evident from the strong correlations between the reading fluency measures in Grades 1, 4, and 8 and from the scatterplot presented in Figure 1. Fully 70% of the children who showed exceptionally slow and laborious reading (more than one standard deviation below the group mean) at the end of Grade 1 still were among the poorest readers of the current sample almost 8 years later. Only 3 children of the very poor first graders managed to develop at least (low) average reading skills later on. Not a single student of this group became an above average reader. Note that at the end of first grade, even the poor readers were well able to carry out the process of phonological decoding. Reading accuracy for words was high: Even the poorest readers were able to decode at least 60% of the nonwords correctly, and errors typically consisted of misreadings of only one letter. It is highly

likely that reading accuracy would have been even higher if the reading tasks had been presented without time pressure. The same word and nonword reading lists were previously used in a European cross-linguistic comparison of reading accuracy at the end of Grade 1 (Seymour, Aro, & Erskine, 2003). In this study, reading material matched for length, frequency, and syllable structure was given to children in 13 different orthographies. Apart from the Scottish and Danish groups (both phonologically rather opaque orthographies), all first-grade samples were at or close to ceiling for both words and nonwords, which confirms that reading accuracy development proceeds rapidly in orthographies with consistent grapheme–phoneme correspondences. The high accuracy in the current sample is actually a methodological advantage, as reading fluency development can be examined independently of accuracy problems.

Similar findings of high reading accuracy in association with a high stability of reading fluency were reported by Klicpera and Schabmann (1993) for another German-speaking sample and by de Jong and van der Leij (2002, 2003) for a Dutch sample. It is often assumed that deficits in word recognition are ultimately due to a delay in the acquisition of phonological decoding skills. Such a delay would prevent children from applying a so-called self-teaching mechanism (Share, 1995) by which unknown words are

decoded a few times until they can be stored in orthographic memory. For the current sample, however, no serious delays in the acquisition of phonological decoding were evident by the end of Grade 1. However, although more or less any grapheme sequence can be decoded with reasonable accuracy, some children could not make use of this self-teaching mechanism as efficiently as the rest of the sample. For these children, Ehri's (2002) statement that "reading the word a few times secures its connections in memory" (p. 11) is not appropriate.

In the current study, we also examined the longitudinal development of spelling skills and found a strong relationship between early problems in phonological spelling units and later orthographic spelling skills. This finding is relevant in two respects. First, it shows that even in the phonologically transparent orthography of German, good competence in translating phonemic segments into a grapheme sequence is indispensable. The main difference from findings in the phonologically much less transparent orthography of English is probably that successful word identification via phonological decoding acts as a learning mechanism, so that understanding how the orthography maps onto spoken words is much easier to acquire and does not pose a serious hurdle to the majority of children. Second, on first glance it is not obvious why early phonological skills should have an influence on orthographic spelling. Orthographic markers in German are only partly phonology based. The different spellings of homophone pairs such as *fiel* (*he fell*) and *viel* (*many*) or *Wahl* (*election*) and *Wal* (*whale*) are obviously not phonologically motivated, as the word pronunciations are identical. Still, children with poor phonological skills seem to be at a serious disadvantage to store orthographic spellings in memory. It is, of course, possible that phonological problems are only an indicator for more general verbal deficits, so that children who show phonological deficits at the beginning of liter-

acy instruction also have deficits in morphosyntactic skills that are relevant in spelling. Another explanation for the relation between early phonological skills and later spelling development is that the build-up of orthographic representations requires the formation of multiple associations between written and spoken words (Ehri, 1992; Perfetti, 1992). Children with phonological deficits might not be able to establish such multiple associations.

In addition to these findings on the long-term stability of reading fluency and spelling, the design of our longitudinal study also allowed us to examine the pattern of early prediction of phonological and naming speed measures for reading and spelling development over the full 8-year period of the study. So that readers interpret the findings adequately, it should once again be mentioned that the phonological awareness task applied in the present study was different from standard measures used in this field. Phonological awareness refers to the explicit access of the sublexical sound structure and is typically assessed by measures that require segmentation or manipulation of sound segments. However, earlier studies in our lab indicated that tasks requiring sound segmentation or manipulation are very difficult for German-speaking children before the onset of reading instruction (Mann & Wimmer, 2002), probably because sound games and reading preparation are largely absent from the preschool system in German-speaking countries. The imitation paradigm applied in the present study showed an adequate level of difficulty and therefore fulfilled the statistical requirements for the regression analyses presented here. An obvious concern is that rote memory of the critical word and its segments may boost performance. However, we note that the correlation between our phonological awareness measure and the phonological short-term memory measure was low. Furthermore, the short-term memory measure was not associated with any of the subsequent reading fluency measures or with the phonolog-

ical spelling measure in Grade 1. The measure was based on the idea that imitating the experimenter should be easier for children who understand that the experimenter is segmenting the simple words presented into functional sound units (i.e., phonemes).

In spite of the unconventional measure of phonological awareness, overall, earlier findings in German, Dutch, and Italian (de Jong & van der Leij, 1999, 2002; Di Filippo et al., 2005; Wimmer & Mayringer, 2002; Wimmer et al., 2000) can be confirmed. While the phonological measures (phonological awareness and phonological short-term memory) dropped out as significant predictors after first grade, naming speed assessed at school entry was a consistent predictor of reading fluency up to Grade 8. These findings seem to be different from findings with English-speaking children, for whom phonological awareness is often reported to be the best predictor of reading development (Cronin & Carver, 1998; Mann & Wimmer, 2002; Torgesen, Wagner, Rashotte, Burgess, & Hecht, 1997). It is possible that this finding was due to the fact that our imitation paradigm is not a phonological awareness task in the narrow sense—that is, children were not required to segment the phonemes of the presented words independently. Another explanation for this difference in findings might be that English studies usually do not assess the development of reading fluency but focus on the development of reading accuracy only. However, Kirby, Parrila, and Pfeiffer (2003) recently reported for a Canadian sample that phonological awareness assessed in kindergarten ceased to be a relevant predictor for word reading accuracy after Grade 2, while the prediction of kindergarten rapid automatized naming was only significant from Grade 3 on. It is thus possible that the same predictive patterns as reported here are also valid for English but that, as the acquisition of competent phonological decoding skills takes about 2 to 3 years longer in the phonologically opaque English orthography than in transparent orthographies such as German (Aro & Wimmer, 2003; Seymour et al., 2003), the change

in predictive strength of phonological awareness and rapid automatized naming takes place later in English than in German.

A methodological limitation of the present findings is the high attrition rate. Only about 35% of the children of the first grade sample still participated in the final assessment. One third of the sample was lost because of missing addresses, but another third was located and chose not to participate. The most likely selection bias for the final assessment is that adolescents with poor literacy skills might have tended to avoid the embarrassment of an assessment of their reading and spelling skills and therefore declined. If this is the case, this effect would certainly restrict the representativeness of our findings. Given the fact that we found no major differences between Grade 8 participants and nonparticipants on the prediction measures, our findings may overestimate the predictive power of our prediction measures if, indeed, the lower end of literacy skills was underrepresented in the Grade 8 sample. In other words, if it was the poorer readers who decided not to participate in Grade 8, they did not have lower scores on the prediction measures than the possibly better readers who did participate. Still, we do not think that such a selective attrition has been going on in our sample, as on the Grade 8 standardized spelling test the average performance corresponded to the 54th percentile. If the lower end of the distribution of literacy skills were missing from our sample, the mean level of performance could be expected to be above average.

In conclusion, the findings of the current longitudinal study, which followed German-speaking children's development of reading fluency and orthographic spelling from the beginning of Grade 1 until Grade 8, confirm once more that for children who start into literacy development with certain risk factors that can be identified easily, the long-term prognosis is strikingly poor. Sometimes children are able to compensate for inefficient word reading skills if they have sufficient time (Walczyk, Marsiglia, Johns, & Bryan,

2004), and therefore reading comprehension is not deleteriously affected. However, the correlation between reading fluency and reading comprehension was still substantial (.64) for the Austrian sample of 15-year-olds participating in the Program for International Student Assessment (Landerl & Reiter, 2002), which indicates that a high percentage of dysfluent readers also experience serious comprehension deficits.

A final comment seems justified on the issue of intervention. We did not assess whether or what kind of intervention the poorer readers in our sample received over the years. If they did receive intervention, it did not induce serious improvements of their reading fluency. Most reading intervention programs today focus on phonological awareness and phonological decoding in reading. Given that phonological awareness is not strongly related to the development of reading fluency and that even the poorer readers of the present study were well able to phonologically decode words and nonwords already at the end of Grade 1, such intervention programs do not seem adequate for the problems these children experienced. Indeed, current evaluations show that such phonology-based programs have positive effects for children with low reading accuracy but that they do not have an influence on these children's low reading fluency (Torgesen, Rashotte, & Alexander, 2001). Serious research efforts are needed to develop and evaluate intervention programs that are specifically tailored to the problems of these dysfluent readers with high reading accuracy. Attempts in that direction (e.g., Levy, 2001; Thaler, Ebner, Wimmer, & Landerl, 2004) show that dysfluent reading is not only a highly stable characteristic but also one that is hard to remediate.

## Low Publication Prices for APA Members and Affiliates

**Keeping you up-to-date.** All APA Fellows, Members, Associates, and Student Affiliates receive—as part of their annual dues—subscriptions to the *American Psychologist* and *APA Monitor*. High School Teacher and International Affiliates receive subscriptions to the *APA Monitor*, and they may subscribe to the *American Psychologist* at a significantly reduced rate. In addition, all Members and Student Affiliates are eligible for savings of up to 60% (plus a journal credit) on all other APA journals, as well as significant discounts on subscriptions from cooperating societies and publishers (e.g., the American Association for Counseling and Development, Academic Press, and Human Sciences Press).

**Essential resources.** APA members and affiliates receive special rates for purchases of APA books, including the *Publication Manual of the American Psychological Association*, and on dozens of new topical books each year.

**Other benefits of membership.** Membership in APA also provides eligibility for competitive insurance plans, continuing education programs, reduced APA convention fees, and specialty divisions.

**More information.** Write to American Psychological Association, Membership Services, 750 First Street, NE, Washington, DC 20002-4242.

# Early First-Language Reading and Spelling Skills Predict Later Second-Language Reading and Spelling Skills

This prospective study examined early first-language (L1) predictors of later second-language (L2) reading (word decoding, comprehension) and spelling skills by conducting a series of multiple regressions. Measures of L1 word decoding, spelling, reading comprehension, phonological awareness, receptive vocabulary, and listening comprehension administered in the 1st through 5th grades were used as predictors of L2 reading (word decoding, comprehension) and spelling skills in high school. The best predictor of L2 decoding skill was a measure of L1 decoding, and the best predictors of L2 spelling were L1 spelling and L1 phonological awareness. The best predictor of L2 reading comprehension was a measure of L1 reading comprehension. When L2 word decoding skill replaced L1 word decoding as a predictor variable for L2 reading comprehension, results showed that L2 word decoding was an important predictor of L2 reading comprehension. The findings suggest that even several years after students learn to read and spell their L1, word decoding, spelling, and reading comprehension skills transfer from L1 to L2.

*Keywords:* L1, L2, reading, spelling, cross-linguistic transfer

Until recently, there was limited interest by foreign (second) language educators and researchers in examining the relationship between first, or native, language (henceforth, L1) skills and the next language to be learned, be it a second language learned in a natural setting or a foreign language learned in a classroom (henceforth, L2). Recently, however, with the proliferation of worldwide migration and the growing awareness of its implications for multilingual societies, researchers have begun to pay attention to L1–L2 connections. In the past few years, there has been an explosion in the number of studies investigating this relationship. In particular, there has been an increased interest in the extent to which L1 factors influence L2 reading development (e.g., see reviews by Geva & Verhoeven, 2000; Koda, 2005) and L2 oral and written proficiency (e.g., see review by Ganschow & Sparks, 2001). However, only a few of these studies have followed students' language performance from their primary school years into high school, at which time students in the United States begin to study an L2.

In this study, we followed students over a 10-year period to determine whether performance on measures of L1 reading (decoding, comprehension), spelling, phonological awareness, vocabulary, and listening comprehension are predictive of L2 reading (word decoding, comprehension) and spelling. Examination of the predictive value of L1 skills in elementary school for L2 skills in high school over a lengthy time period might provide useful information to researchers interested in issues of long-term cross-linguistic transfer of reading and spelling skills with older students learning an L2 years after they had acquired L1 reading and spelling skills. From a practical perspective, there may also be issues of interest for the prediction of L2 learning under different social and motivational contexts, for example, additive versus subtractive bilingualism, and for the diagnosis and possible prevention of reading and spelling problems in the L2.

## L1–L2 Relationships

Researchers have speculated that there is a relationship between students' L1 and L2 skills. Cummins (1979, 1984) developed the linguistic interdependence hypothesis, in which he argued that language and literacy skills can be transferred from one language to another. His primary contention was that success in the L2, for example, reading, depended on previous competence in L1 literacy skills. Researchers investigating Cummins's (1979, 1984) hypothesis have provided evidence of the interdependence of L1 and L2 skills among school-age English learners (e.g., see Cummins & Mulchay, 1978; Legarretta, 1979). In their linguistic coding differences hypothesis, Ganschow and Sparks (2001) proposed that

L1 skills serve as the foundation for L2 learning and that problems with one component of language (e.g., phonological processing) are likely to have a negative effect on both L1 and L2 learning (e.g., see Sparks, 1995; Sparks & Ganschow, 1993). Their studies have shown that L2 learners in high school who achieve higher levels of oral (listening, speaking) and written (reading, writing) L2 proficiency and classroom achievement (grades) have significantly stronger L1 ability, especially phonological processing skills, than do L2 learners with lower levels of L2 proficiency and achievement (e.g., see Sparks et al., 1998; Sparks, Ganschow, Artzer, Siebenhar, & Plageman, 1998). In a recent study, Sparks, Humbach, and Javorsky (in press) found that high school students who had significant differences in L2 oral and written proficiency, word decoding, and spelling exhibited significant differences in their L1 literacy skills as early as the fourth grade. In another study, Sparks, Patton, Ganschow, Humbach, and Javorsky (2006) found that L1 reading and spelling skills in elementary school were the best predictors of oral and written L2 proficiency in high school.

Studies by other researchers have also found a strong relationship between L1 skills and L2 proficiency in a variety of languages. Dufva and Voeten (1999) tested 160 Finnish students at the beginning of the first grade and followed them into the third grade, when they started to learn English. They verified that both L1 literacy and phonological memory skills were predictive of L2 learning. Olshtain, Shohamy, Kemp, and Chatow (1990) discovered that L1 academic proficiency played the most important role in L2 learning among a group of Hebrew-speaking students learning English. In a recent study with U.S. college students, Meschyan and Hernandez (2002) found that L1 decoding skills predicted college-age adults' L2 competency and that this relationship was mediated by participants' L2 word decoding skills. They also found that L1 decoding skill was an important predictor of grades in introductory L2 courses. Other investigators have obtained findings similar to the aforementioned studies (e.g., Holm & Dodd, 1996; Hulstijn & Bossers, 1992; Humes-Bartlo, 1989; Kahn-Horwitz, Shimron, & Sparks, 2005, 2006).

### L1-L2 Decoding

Related research on the processes by which students learn to read their L1 provides potential insights that assist our understanding about the role of decoding in learning to read an L2. There is considerable research evidence indicating that students who become skilled readers are those who read (decode) words accurately and fluently (see reviews by Rayner, Foorman, Perfetti, Pesetsky, & Seidenberg, 2001; Wolf, 2001). Learning to read words requires knowledge of phonological awareness, letter-sound correspondences, and orthographic patterns (Snow, Burns, & Griffin, 1998). In turn, accurate word decoding skills enable students to read most words in the text to comprehend its meaning (Ehri, 2005). Longitudinal research has shown that the ability to read words in the first grade predicts reading-related skills 11 years later (Cunningham & Stanovich, 1997; MacDonald & Cornwall, 1995).

In contrast to the voluminous research conducted on L1 word decoding, Koda (2005) has reported that L2 word decoding has received little attention from researchers for two reasons.<sup>1</sup> First, top-down conceptualizations of L2 reading (e.g., see Bernhardt, 1991) have dominated L2 research in the past. Second, linguistic

knowledge has often been equated with language processing skills (e.g., see Bialystock, 2001). Thus, reading skills, and specifically word decoding, were thought to develop concurrently with increased knowledge of the L2. However, little or no theoretical support has been found for this hypothesis.

Recent studies have found that L1 phonological awareness is a good predictor of subsequent reading and decoding skills in another language, that is, cross-linguistic transfer (Durgunoglu, 2002). Investigations of cross-linguistic transfer in the development of literacy skills have shown that phonological awareness skills are correlated across languages, particularly with word recognition skills across languages (e.g., see Cisero & Royer, 1995; Geva, Yaghoub-Zadeh, & Schuster, 2000). For example, examining English-language learners whose L1 was Spanish, Lindsey, Manis, and Bailey (2003) found that phonological awareness skills transferred from Spanish to English and predicted word recognition skills in English. In another study with English-speaking children in French immersion classes, Comeau, Cormier, Grandmaison, and Lacroix (1999) confirmed that phonological awareness in both languages was associated with increases in skill at decoding French words.

L2 researchers have also conducted studies comparing high- and low-proficiency L2 readers on word decoding tasks. In one set of studies, low-proficiency readers exhibited slow and less accurate performance on word decoding tasks (e.g., see Favreau & Segalowitz, 1982; Haynes & Carr, 1990). In another group of studies, low-proficiency L2 readers relied less on discourse-level and more on word-level processing (Cziko, 1980; Horiba, 1990) and on a word's graphic cues rather than on semantic information (Chamot & El-Dinary, 1999; Clarke, 1980). The findings suggest that similar to poor L1 readers, poor L2 readers with weak word decoding skills may spend more time sampling visual information than using multiple information sources (Koda, 2005). In other studies, Segalowitz and his colleagues verified that fluent bilingual speakers displayed large variations in their word decoding fluency (Favreau & Segalowitz, 1983; Segalowitz, 1986; Segalowitz, Poulson, & Komoda, 1991). Such findings imply that word decoding skills develop independently of oral language competence, and the acquisition of oral language in the L2 does not ensure development of word recognition skills. Moreover, longitudinal studies with school-age L2 learners have revealed no systematic link between L2 word reading skills and L2 oral language proficiency (August, Calderon, & Carlo, 2001; Gholamain & Geva, 1999).

Recent studies have also shown that the orthographic depth of the L2 (i.e., orthographies with highly regular sound-symbol relationships vs. orthographies that preserve morphological information at the expense of phonological transparency), the orthographic distance between the L1 and L2 (i.e., similarities and dissimilarities in L1-L2 writing systems), and L1 experience and knowledge contribute to skill in L2 word decoding. In their orthographic depth hypothesis, Katz and Frost (1992) proposed that the orthographic depth, that is, shallow versus deep orthographies, of a written language affects word decoding skill. Shallow (transparent) or-

<sup>1</sup> Koda (2005, p. 29) distinguished between *word recognition* (i.e., "the process of obtaining words' sounds and meanings") and *decoding* (i.e., "extraction of phonological information"). In this article, the two terms are used interchangeably.

thographies map consistently the sounds of a language with a specific symbol; however, deep (opaque) orthographies have more variable sound–symbol correspondences and can map a sound with more than one symbol. Cross-linguistic studies with L2 learners have found that they achieve faster and more accurate L2 word recognition skills if the L2 orthography is more closely related to their L1 orthography (e.g., see Akamatsu, 1999; Koda, 1999; Muljani, Koda, & Moates, 1998). Other studies have found that L2 learners use identifiable L1 processing skills for L2 word decoding (e.g., see Brown & Haynes, 1985; Ryan & Meara, 1991). In one study, Koda (1990) discovered that learners of English as a second language (ESL) were able to read phonetically accessible nonsense words but not phonetically inaccessible (Sanskrit) ones. Her findings corroborate research that has found that L2 learners with different orthographic backgrounds use distinct processing skills to read words. She concluded that L1 orthographic experience has an impact on L2 lexical processing and that L1 processing is a major source of variance among L2 learners' word decoding skills (see Koda, 2005).

### L1–L2 Spelling

Research on the processes by which students learn to spell their L1 also provides potential insights about the role of L1 spelling skills in learning to spell an L2. In the L1, researchers have revealed that phonological awareness skills are highly correlated with spelling ability (Bruck & Treiman, 1990; Stuart & Masterson, 1992) and that children's ability to spell is also related to knowledge of phonological processing and letter–sound correspondences in that sounds map onto letters (e.g., see Moats, 2005; Treiman, 1993). Frith (1980) proposed that spelling is “visible phonology” (p. 2) and that it also reflects other levels of language, chiefly visual or orthographic factors.

Investigations of the development of L2 spelling skills have examined how phonological processing in the L1 affects spelling skills in the L2. In a study with ESL learners, Wade-Woolley and Siegel (1997) showed that spelling skills in the L2 were associated with phonological processing skills, but students' reading skill in the L2 had a more significant influence on spelling accuracy than their L1 skills. In a study with L1 and minority (immigrant) children learning to read and spell in an L2 in the Netherlands, Verhoeven (2000) found that although the minority children were less efficient in various reading and spelling processes in Dutch than were their native Dutch peers, L1 and L2 readers and spellers relied on highly comparable strategies. In addition, orthographic factors also are likely to influence spelling performance. For example, Treiman (1993) has shown that children are sensitive at an early age to the orthographic structures in the spellings of words. In a review of several studies on basic processes in early L2 reading and spelling, Geva and Verhoeven (2000) concluded that, “L1–L2 transfer at the level of underlying component skills such as phonological awareness relates to word recognition and spelling” (p. 265).

### L2 Reading Comprehension

Although new findings in L2 reading research have shown that readers must decode words efficiently to comprehend text in the L2, there is still debate about the precise contributions of lower

order or bottom-up and higher order top-down processes for L2 reading comprehension (Koda, 2005). In L1 research, Cutting and Scarborough (2006) reviewed evidence that showed that both bottom-up, that is, accurate word decoding, and top-down, that is, proficient use of semantic and syntactic relationships for understanding the meaning of text, are necessary for skilled reading comprehension. Koda (1992) has noted that most investigations of L2 reading have focused on higher order processes, such as linguistic knowledge, background knowledge, and cognitive and metacognitive skills, in explaining reading comprehension skills. In her reviews of the L1 and L2 research literature, however, she found that inefficient and slow word decoding in the L2 plays a significant role in L2 reading comprehension (Koda, 1998) and concluded that decoding skills are a “precondition” for L2 comprehension (Koda, 2005, p. 256). In recent years, some L2 studies have reported positive correlations between lower order (decoding) skills and reading comprehension (Hirai, 1994; Nassaji & Geva, 1999). In one study, VanGeldereren et al. (2004) found that although the componential structures of L1 and L2 reading comprehension are not identical, L1 reading comprehension made a large contribution to L2 reading comprehension. Fukkink, Hulstijn, and Sims (2005) found that although L2 word decoding is important for L2 reading comprehension, there may not be a strong causal link between an “increase of lexical access, beyond a certain threshold that has yet to be determined, and reading comprehension” (p. 72). They concluded that automatic lexical access helps in processing words in the text, but there are many processes operating simultaneously that contribute to efficient L2 reading comprehension. In a study of fourth-grade learners of English as a foreign language, Proctor, Carlo, August, and Snow (2005) showed that both L2 oral language skills (vocabulary knowledge, listening comprehension) and L2 word decoding skills (alphabetic knowledge, fluency) are important for L2 reading comprehension.

### Summary and Hypotheses

Evidence indicates that students' facility with reading and spelling in the L1 is related to their learning to read and spell in L2, demonstrating cross-linguistic transfer of skills. However, the assertion that L1 reading and spelling skills in elementary school have an effect on L2 reading and spelling skills in high school several years later would entail long-term cross-linguistic transfer of L1 skills to the L2. Koda (2005) described the impact that connectionist views of reading acquisition have had on research and thinking about the development of L2 reading skills. In the connectionist model, units are linked to one another to form a network. Retrieval of specific activation patterns stored in memory (i.e., letter strings, letter–sound correspondences) is effortless and is likely to be activated by L2 input, regardless of the orthographic distance between L1 and L2. In her view, the connectionist model of automaticity establishes a rationale for predicting “procedural variations stemming from L1 skill activation among L2 readers with diverse backgrounds” (Koda, 2005, p. 18). The connectionist model offers a way to study and analyze L2 reading competence and its development because the ability to read an L2 requires the ability to “map between language forms and their functions. . . with increased experience in the L2, form–function mapping procedures are activated automatically irrespective of the learner's intention” (Koda, 2005, p. 18).

Building on the connectionist framework, we propose that because the fundamental competencies—decoding and comprehension—are the same in L1 and L2 reading, there is reason to expect that there will be long-term cross-linguistic transfer of L1 reading and spelling skills developed in elementary school to L2 reading and spelling skills several years later when learners first encounter an L2 in high school. Specifically, students' decoding and spelling skills in their alphabetic L1 (English) will likely account for a large part of the variance in their decoding and spelling skills in an alphabetic L2 (Spanish, French, German). Likewise, L1 decoding and L1 reading comprehension skills will likely account for part of the variance in L2 reading comprehension skills. However, as students' exposure to the L2 increases over 2 years of L2 study in high school, their L2 decoding skill may account for a larger part of the variance in L2 reading comprehension than either their L1 decoding or L1 reading comprehension skills.

The present study is one part of a larger prospective investigation conducted with the participants. In a previously published study Sparks et al. (2006) examined the best predictors of overall L2 proficiency (i.e., listening comprehension + speaking + writing + reading comprehension) and of L2 aptitude measured by a standardized L2 aptitude test, the Modern Language Aptitude Test (Carroll & Sapon, 1959). The study reported here differs from the aforementioned study by specifically examining the role of L1 skills, that is, word decoding, reading comprehension, spelling, receptive vocabulary, and listening comprehension, in predicting students' L2 word decoding, reading comprehension, and spelling skills rather than their overall oral and written L2 proficiency. It also differs by investigating the long-term prediction of L2 reading and spelling skills.

## Method

### Participants

The participants were 54 high school students, 25 male and 29 female, from a large middle-class rural school district in the Midwest. All of the students had completed 2 years of L2 study in one of three languages—Spanish ( $n = 30$ ), French ( $n = 14$ ), and German ( $n = 10$ ). The students were followed from the 1st through the 10th grades. All of the participants completed their second year of the L2 by the end of the 10th grade. The mean age of the participants at the beginning of the 1st grade was 6 years, 9 months; at the end of the study 10 years later, the mean age of the participants was 16 years, 4 months (age range = 15 years, 9 months to 16 years, 11 months).<sup>2</sup> All of the students were Caucasian. The study began with 156 students when they entered 1st grade in this school district. By the 9th grade, 101 of the 156 students still attended school in the district. Seventy-seven of the 101 students began to learn an L2 in the 9th grade. Fifty-four of the 77 students chose to continue their participation in the study when they began their first year in an L2 course. Parental permission was obtained for each participant.

Resources were not available to test all 1st-grade students enrolled in the district's elementary school in a given year. However, we wanted to obtain a sample of students who would be likely to take an L2 course in high school and to exhibit a range of academic achievement skills. Therefore, we chose a cohort model and used a sample of good, average, and below average readers over a

3-year period. The 54 participants were chosen in the following manner. The school district administered a reading readiness measure, the Test of Reading Readiness: Level K (Scott, Foresman and Company, 1987) to all of its kindergarten students each year. On the basis of their scores on this measure (raw scores ranged from 0 to 34) and the kindergarten teacher's recommendation, students were assigned by the school to one of three types of 1st-grade classrooms: (a) above average readers, (b) at-risk readers, and (c) average readers. In the school, there was one class for above average readers, one class for at-risk readers, and several classes for average readers each year. For each of the three cohorts, we invited all of the students in the above average class and the at-risk class to participate in the study. On the Test of Reading Readiness: Level K, the above average students had achieved raw scores ranging from 33 to 34 and the at-risk students had achieved raw scores ranging from 0 to 16. A random sample of students in the average reading classes whose score on the reading readiness measure ranged from 17 to 33 were selected to take part in the study. Of the 54 students who participated for all 10 years of the study, 18 (33.3%) were above average readers, 19 (35.2%) were average readers, and 17 (31.5%) were at-risk readers. There were similar numbers of students in each of the three cohorts (Cohort 1 = 17 students, Cohort 2 = 20 students, Cohort 3 = 17 students).

## Instruments

### Measures of L1 Proficiency

**Word decoding.** The measure of L1 word decoding was the Woodcock Reading Mastery Test—Revised Basic Skills Cluster, Forms G and H (Woodcock, 1987). The Basic Skills Cluster is composed of two subtests, Word Identification and Word Attack. On the Word Identification subtest, a student read aloud a list of increasingly difficult words. On the Word Attack subtest, a student read aloud a list of increasingly difficult pseudowords. For a response to be considered correct, the student had to produce a natural reading (pronunciation) of the word or pseudoword. A test-retest reliability of .96 was reported for the Basic Skills Cluster.

**Spelling.** The measure of L1 spelling was the Test of Written Spelling—2 (Larsen & Hammill, 1986). On this dictated word test, the student wrote the words spoken by the examiner. The response was marked as correct or incorrect. A test-retest reliability of .95 was reported for this test.

**Reading comprehension.** The measure of L1 reading comprehension was the Formal Reading Inventory, Forms A and B (Wiederholt, 1986). On this multiple-choice test, the student answered five questions after reading silently a short paragraph. The response was marked as correct or incorrect. Internal consistencies of .92 to .97 were reported for the two forms of the test used in this study.

**Phonological awareness.** The measure of L1 phonological awareness was the Lindamood Auditory Conceptualization Test, Forms A and B (Lindamood & Lindamood, 1979). On this test, the student manipulated blocks of various colors to indicate his or her

<sup>2</sup> We extend special thanks to Jackie Blair for her crucial role as facilitator and school liaison in this study. The study could not have been completed without her assistance.

conceptualization of speech sounds spoken by the examiner. The student showed the number, sameness, or difference of sounds (e.g., show me /b/ /b/ /z/) and represented with the blocks changes in spoken patterns without associating the sounds with letters (e.g., if that says *ups*, show me *usp*). This test yielded raw scores with a range of 0 to 100. Pretest–posttest reliability of .96 was reported for the two forms of the test.

*Reading readiness.* The measure of reading readiness was the Test of Reading Readiness: Level K. The test consists of two parts, each of which had several subtests. In this study, Part 2, Level B was used to gauge reading readiness. Level B consisted of four subtests: the Auditory Discrimination/Rhyme subtest tested the ability to listen to a spoken word (“dish”) and match a picture that rhymed (*fish*); the Letter/Sound Relationships subtest tested the ability to look at a letter (*w*), know its sound (/w/), and match the sound with a picture that started with the same sound (*worm*); the Word Recognition subtest tested the ability to listen to three words (“dog,” “does,” “blue”) and to circle the written word with a different initial sound than the others (*blue*); and the Sentence Reading subtest tested skill for choosing the correct written sentence (out of two sentences) that matched the action in an accompanying picture. The four subtests produced a raw score with a range of 0 to 37. A test–retest reliability of .90 was reported.

*Vocabulary.* To assess L1 vocabulary, the Peabody Picture Vocabulary Test—Revised, Forms L and M (Dunn & Dunn, 1981) was used. The test measured receptive vocabulary for standard American English. On this test, the student was shown four pictures and asked to identify the picture for the word spoken by the examiner. The response was marked as correct or incorrect. A median test–retest reliability of .82 was reported for the two forms of the test.

*Listening comprehension.* The Woodcock Reading Mastery Test—Revised Passage Comprehension subtest, Forms G and H (Woodcock, 1987) was used to appraise L1 listening comprehension. This cloze test consists of reading a short passage (one–two sentences) aloud to a student and asking him or her to identify aloud a key word missing from the passage. The student was not permitted to read (see) the passage, but the passage could be repeated. Again, the response was marked as correct or incorrect. This subtest is generally used as a measure of reading comprehension; however, the aforementioned alternative procedure was recommended by Aaron (1989) as a diagnostic indicator in identifying problem readers and was used for this study. A test–retest reliability of .92 when used as a measure of reading comprehension was reported for the two forms of this subtest.

Each of the preceding L1 achievement measures was chosen to examine whether the processes used in learning to read and spell the L1 would be important for learning to read (decode, comprehend) and spell the L2 several years later. The L1 phonological awareness, reading readiness, and word decoding measures were expected to correlate with a measure of L2 word decoding. The L1 phonological awareness and spelling measures were expected to correlate with a measure of L2 spelling. The L1 reading comprehension, listening comprehension, and vocabulary measures were predicted to correlate with a measure of L2 reading comprehension.

## *Measures of L2 Word Decoding, Spelling, and Reading Comprehension*

Nonstandardized L2 tasks of word decoding, spelling, and reading comprehension in Spanish, French, and German were designed by three L2 educators who had expertise in their language of study. L2 proficiency measures are not standardized and do not yield standardized scores for comparison purposes. Instead, the proficiency guidelines developed by the American Council for the Teaching of Foreign Languages (ACTFL; ACTFL, 1989) list levels of proficiency that range from novice–low to superior. The guidelines do not distinguish between oral versus written expression or reading versus writing and do not include word decoding and spelling as separate proficiency skills.

*L2 word decoding.* The word decoding task for each of the three languages consisted of a list of 20 actual words and a list of 20 pseudowords. The real and pseudowords in the three L2s measured a specific decoding task that involved use of vowel sounds in each L2 that were not consistent with the vowel sounds in English. The vowel sounds in the L2s used different letter combinations and contained multisyllabic words and words with diacritical markings. Each student read aloud the list of real words and pseudowords. For a response to be considered correct, the student had to pronounce the word correctly. If the student spontaneously self-corrected a response, then that response was counted as correct. The reliability of the L2 word decoding lists and pseudoword lists was checked by calculating Cronbach’s alpha. For the Spanish words, the reliability coefficient for the word decoding list was .75 and for the pseudoword decoding list was .75. For the French words, the reliability coefficient for the word decoding list was .78 and for the pseudoword decoding list was .84. For the German words, the reliability coefficient for the word decoding list was .81 and for the pseudoword decoding list was .79. The word lists in the three L2s are presented in Appendix A.

*L2 spelling.* The L2 spelling task for each of the three languages consisted of 20 words designed to measure a specific decoding task. Like the word decoding tasks, this measure included vowel sounds in the L2 that were not consistent with the vowel sounds in English, used different letter combinations, and contained multisyllabic words and words with diacritical markings. The students wrote the words spoken by the examiner, and their responses were marked as correct or incorrect. The reliability of the L2 spelling lists was checked by calculating Cronbach’s alpha. For the Spanish words, the reliability coefficient was .78, for the French words, the reliability coefficient was .81, and for the German words, the reliability coefficient was .74. The spelling lists are presented in Appendix B.

*L2 reading comprehension.* The L2 reading comprehension measure tested students’ comprehension using the ACTFL proficiency guidelines (ACTFL, 1986, 1989). The L2 reading comprehension test was designed using criteria descriptive of the intermediate–high level of the ACTFL guidelines. The reading comprehension test in Spanish used the same items and prompts as the French and German tests. Students read silently a one-page letter written in the L2 and answered 10 multiple-choice questions in English about the letter by circling the correct answer. The students were then given a passage to read silently from *Reader’s Digest* in Spanish, French, or German and were asked to answer 10 multiple-choice questions in English about the passage by circling

the correct answer. The only differences in the three reading comprehension tests were those specific to a particular L2. The test directions and time limits were the same for each of the three L2s. The comprehension questions were not ordered by degree of difficulty. The Cronbach's alpha was .52.

### Procedure

Four of the L1 measures (i.e., Woodcock Basic Skills Cluster, Test of Written Spelling—2, Formal Reading Inventory, and Peabody Picture Vocabulary Test—Revised) were administered in elementary school at five different time intervals: at the beginning of the first grade and the end of first, second, third, and fifth grades. The Lindamood Auditory Conceptualization Test was administered only through the third grade, and the listening comprehension test (Woodcock Passage Comprehension subtest) was administered only at the end of the third and fifth grades. For each of the L1 measures, a student's scores were combined across years (i.e., first through fifth grades) to obtain a mean score on each measure. The L1 measures were administered by Richard L. Sparks and Leonore Ganschow, with assistance from undergraduate and graduate students trained prior to administration of the tests.<sup>3</sup> Scores on the reading readiness measure, the Test of Reading Readiness: Level K, were obtained from school records at the end of the first and second grades.

The L2 word decoding measure was administered individually to each student at the end of the 9th- and 10th-grade years by Nancy Humbach and graduate students trained by her.<sup>4</sup> For the L2 word decoding measure, the student read the word lists twice, once at the end of the first-year L2 course and again at the end of the second-year L2 course. The maximum score for the first-year (9th grade) L2 word decoding measure was 40 words (20 real words and 20 pseudowords); likewise, the maximum score for the second-year (10th grade) L2 word decoding measure was 40 words. The students' performance for each of the 2 years was analyzed separately because we speculated that their performance on the word lists might increase as they became more familiar with the L2 being studied.

The L2 spelling measure was given individually to each student at the end of the 10th-grade year by Nancy Humbach and graduate students trained by her. The student wrote each word on a piece of paper as the examiner read the word aloud. The examiner repeated a word as often as necessary. The maximum score on the spelling test was 20 words.

The L2 reading comprehension measure was administered in groups by Richard L. Sparks at the end of the students' second-year L2 course. The students were given 15 min to read the letter and answer the questions and 15 min to read the *Readers Digest* passage and answer the questions. The maximum score for the assessment was 20.

Analyses of variance were used to determine whether there were significant differences among the three different L2 groups (Spanish, French, and German) on the four L2 measures. Findings showed that there were no significant differences among the three L2 groups on the L2 word decoding test, Year 1,  $F(2, 51) = 0.05$ ,  $p = .95$ ; the L2 word decoding test, Year 2,  $F(2, 51) = 0.73$ ,  $p = .49$ ; the L2 spelling test,  $F(2, 51) = 1.25$ ,  $p = .30$ ; and the L2 reading comprehension test,  $F(2, 51) = 1.34$ ,  $p = .27$ .

### Results

Table 1 reports the mean scores of the 54 participants on the L1 variables. For the L2 measures, the mean score on the L2 word decoding measure at the end of the first-year L2 course was 20.7 ( $SD = 6.4$ ); at the end of the second-year L2 course, the students' mean score on the L2 word decoding measure was 25.7 ( $SD = 7.1$ ). The mean score of the 54 students on the L2 spelling measure at the end of the second-year L2 course was 8.8 ( $SD = 3.6$ ). The mean score of the 54 students on the L2 reading comprehension measure at the end of the second-year L2 course was 10.2 ( $SD = 3.0$ ). Table 2 presents intercorrelations among the L1 and L2 measures for the total group.

Four separate analyses were conducted to determine which L1 variables in elementary school were the best predictors of L2 word decoding, Year 1; L2 word decoding, Year 2; L2 spelling; and L2 reading comprehension in high school. Two additional analyses were then conducted in which the L2 decoding measures replaced the L1 decoding test to predict L2 reading comprehension. In the first analysis, the L2 word decoding, Year 1 measure replaced the L1 decoding measure, Woodcock Basic Skills Cluster, as a predictor variable for L2 reading comprehension. In the second analysis, the L2 word decoding, Year 2 test replaced L2 word decoding, Year 1 (and Woodcock Basic Skills Cluster) as a predictor variable for L2 reading comprehension.

Multiple regression analyses using the maximum  $R^2$  improvement (MAXR) technique for variable selection was applied to determine which variables were important predictors of L2 word decoding, L2 spelling, and L2 reading comprehension. This procedure is sometimes used on data sets of smaller size so that relationships of interest that may exist in the population might not be overlooked. The MAXR first calculates the best one-variable model (i.e., which single measure best correlates with a specific outcome variable). Then, the best two-variable model is selected on the basis of the maximum  $R^2$  (coefficient of determination) improvement. The best two-variable model indicates the two measures that explain the highest percentage of the variance in L2 proficiency about its mean. This process continues by determining the best three-variable model yielding the largest  $R^2$  improvement and so on, until a model containing all the measures as predictors of an outcome variable is generated. Unlike the traditional stepwise selection methods (e.g., forward selection, backward elimination, stepwise regression) that provide one best variable model, the MAXR procedure provides several alternative models from which to choose and does not perform any inferential tests in selecting its best models. To ascertain the size of the best model to select, Mallow's  $C_p$  statistic was used. The model having a  $C_p$  statistic that is less than the number of predictors allows the choice of a model having a small mean square error and small regression bias. The mean square error gauges the average squared deviation between the actual score on an outcome variable for a student and the score predicted by the regression procedures, taking into account the degrees of freedom in the data. A model with minimal

<sup>3</sup> We extend special thanks to Chris Utter and her staff for their very important roles in the completion of this study.

<sup>4</sup> We thank Kelly Noe and Johannes Tokarski for administering the (real) word decoding, pseudoword decoding, and spelling measures to Cohorts 2 and 3.

Table 1  
*Means (and Standard Deviations) of Participants on the First Language (L1) Measures*

Measure	<i>M (SD)</i>	Minimum	Maximum
Woodcock Basic Skills Cluster <sup>a</sup>	102.0 (12.5)	68.4	131.6
Test of Written Spelling—2 <sup>a</sup>	95.9 (11.6)	75.2	124.2

<sup>a</sup> Standard scores, *M* = 100, *SD* = 15. <sup>b</sup> *z* scores.

regression bias has strong predictive power on observations not necessarily included in the sample from which the model is based. The final model chosen is the one having all of the variables that show mild or strong significance and are not suppressors.

For the prediction models, a tolerance diagnostic was computed for each predictor variable to determine whether multicollinearity among the variables might exist. A tolerance of less than .10 would indicate the presence of significant multicollinearity problems (Mendenhall & Sincich, 1989). The tolerance was at or greater than .26 (range = .26–.70).

*L2 Word Decoding, Year 1*

The analysis yielded a one-variable model in which the best predictor was the Woodcock Basic Skills Cluster ( $\beta = .72$ ),  $F(1, 52) = 57.16$ ,  $p < .0001$ . The Woodcock Basic Skills Cluster alone accounted for 52% of the variance.

*L2 Word Decoding, Year 2*

The analysis produced a one-variable model in which the best predictor was the Woodcock Basic Skills Cluster ( $\beta = .65$ ),  $F(1, 52) = 38.71$ ,  $p < .0001$ . The Woodcock Basic Skills Cluster accounted for 43% of the variance in the model.

Table 2  
*Intercorrelations Among First Language (L1) Variables, Second Language (L2) Word Decoding, L2 Reading Comprehension, and L2 Spelling*

11. L2 reading comprehension											—

\*  $p < .05$ . \*\*  $p < .01$ .

*L2 Spelling*

The analysis generated a two-variable model in which the best predictors were the Test of Written Spelling—2 ( $\beta = .45$ ) and the Lindamood Auditory Conceptualization Test ( $\beta = .36$ ),  $F(2, 51) = 29.93$ ,  $p < .0001$ . The two variables accounted for 54% of the variance in the model. The Test of Written Spelling—2 alone accounted for 47% of the variance. Both variables were significant at the  $p < .01$  level.

*L2 Reading Comprehension (With Only L1 Measures as Predictor Variables)*

The analysis yielded a one-variable model in which the best predictor was the Formal Reading Inventory ( $\beta = .50$ ),  $F(1, 52) = 17.56$ ,  $p < .0001$ . The Formal Reading Inventory accounted for 25% of the variance.

*L2 Reading Comprehension (With L2 Word Decoding, Year 1 Replacing the Woodcock Basic Skills Cluster)*

The analysis yielded a two-variable model in which the best predictors were the Formal Reading Inventory ( $\beta = .34$ ) and L2 word decoding, Year 1 ( $\beta = .28$ ),  $F(2, 51) = 11.16$ ,  $p < .0001$ . The two variables accounted for 31% of the variance in the model. The Formal Reading Inventory alone accounted for 25% of the variance and was significant at the  $p < .05$  level. The L2 word decoding, Year 1 measure approached significance ( $p = .056$ ).

*L2 Reading Comprehension (With L2 Word Decoding, Year 2 Replacing L2 Word Decoding, Year 1 and the Woodcock Basic Skills Cluster)*

The analysis yielded a one-variable model in which the best predictor was L2 word decoding, Year 2 ( $\beta = .62$ ),  $F(1, 52) = 33.12$ ,  $p < .0001$ . The L2 word decoding, Year 2 measure alone accounted for 39% of the variance.

Discussion

This study examined the role of L1 skills (i.e., word decoding, phonological awareness, reading comprehension, spelling, recep-

tive vocabulary, and listening comprehension) in predicting L2 word decoding, spelling, and reading comprehension for high school students who had learned to read and spell their L1 several years earlier. In addition, the study examined whether L2 word decoding skill was important for predicting L2 reading comprehension. The results are discussed under the following headings: *L2 Word Decoding*, *L2 Spelling*, and *L2 Reading Comprehension*.

### *L2 Word Decoding*

The results of the regression analyses showed that the measure of L1 word decoding, the Woodcock Basic Skills Cluster, was the best predictor of L2 word decoding at the end of the first- and second-year L2 courses. In both years, L1 decoding skills at the end of the second, third, and fifth grades accounted for the largest part of the variance in L2 word decoding skills from several years later in high school. These findings are consistent with a growing body of research that has confirmed that the skills used to read words in the L1 are highly correlated with the skills used to read words in an L2 (e.g., see Geva, Wade-Woolley, & Shany, 1997; Kahn-Horwitz et al., 2006; Muljani et al., 1998). Moreover, the finding that students' performance on a measure of L1 decoding skill was related to L2 word decoding is consistent with studies that have revealed a relationship between L1 literacy skills and subsequent performance in L2 learning (e.g., see Dufva & Voeten, 1999; Geva et al., 1997; Meschyan & Hernandez, 2002; Sparks, Ganschow, et al., 1998) and supports the hypothesis that there is long-term cross-linguistic transfer of L1 phonological processing skills to L2 word decoding.

At the end of the first-year L2 course, L1 decoding skill accounted for over half (52%) of the variance in L2 word decoding; at the end of the second-year L2 course, L1 decoding skills accounted for just under half (43%) of the variance in L2 decoding skills. These observations give rise to an important question: Which factors might account for the remaining variance in L2 word decoding? Koda (2005) reported that processes other than phonological coding are used to decode L2 words. For example, she reviewed evidence that showed that a student's facility and subsequent experiences with his or her L1 may account for some of the variance in L2 decoding skills. She also noted that the orthographic distance between the L1 and L2 may account for some of the quantitative variations in L2 decoding skills (e.g., see Akamatsu, 1999; Muljani et al., 1998). A related question is why L1 decoding skills on the Woodcock Basic Skills Cluster explained more of the variance in first-year L2 word decoding than did second-year L2 word decoding skills, a finding that might be explained by the orthographic distance between the students' native language, English, and the three L2s they studied in high school. As the students received more exposure to written words in Spanish, French, or German from Year 1 to Year 2 of their high school L2 courses, they may have become more skillful in their use of strategies for decoding words in Spanish, French, or German. For example, students enrolled in Spanish may have become more accustomed to the regularity of the letter-sound correspondences for vowel sounds in Spanish and also to consonant sounds (e.g., *ll* = /y/) and vowel digraphs (e.g., *ua* = /wä/) that are unique to Spanish. With increased practice and exposure to the L2 orthography, they may have become more skillful in decoding words in the L2.

Another hypothesis for the aforementioned finding is that the three L2s in this study are more transparent orthographies than English. In their orthographic depth hypothesis, Katz and Frost (1992) proposed that phonological information is assembled through letter-by-letter translation in shallow orthographies but that in deep orthographies, phonological information is obtained after a word has been identified on the basis of stored knowledge of the word. In contrast to English, Spanish and German are shallow orthographies in which letters correspond to one phoneme. Although French is more opaque than Spanish and German, students in the three L2s may have learned the three orthographies well enough to rely less on their L1 experiences in English by the second year of the L2 course.

### *L2 Spelling*

The results indicated that the measure of L1 spelling, the Test of Written Spelling—2, was the best predictor of L2 spelling at the end of the second-year L2 course. Students' L1 spelling skills in elementary school explained 47% of the variance in L2 spelling in the 10th grade, which suggests that L1 spelling skills are used for learning to spell words in the L2 even after students learned to spell their L1 many years earlier. These findings are consistent with research that has shown that the component processes underlying L1 and L2 spelling are "highly comparable at the word level" (Verhoeven, 2000, p. 327).

In the prediction model, a measure of L1 phonological awareness in elementary school, the Lindamood Auditory Conceptualization Test, also contributed statistically to the variance in L2 spelling at the end of the second-year L2 course several years later. Phonological awareness (knowledge of the internal sound structure of spoken words) is one of the best predictors of learning to read, not only in English but also in several alphabetic languages (e.g., see Bradley & Bryant, 1983; Lundberg, Olofsson, & Wall, 1980; Rayner et al., 2001; Wagner & Torgesen, 1987). Likewise, phonological awareness skill is highly correlated with spelling ability (Bruck & Treiman, 1990; Stuart & Masterson, 1992). The fact that L1 phonological awareness in elementary school was predictive of L2 spelling ability several years later in high school suggests that long-term transfer of phonological awareness skill is important for spelling and decoding words in an alphabetic L2.

L1 spelling and phonological awareness skills accounted for just over 54% of the variance in L2 spelling skills. The findings for the prediction of L2 spelling are similar to those for L2 word decoding in this study; that is, skills related to phonological processing also accounted for approximately half of the variance in L2 word decoding. Like L2 word decoding, the additional variance in L2 spelling skills might be explained by the students' facility and experiences with their L1, which is consistent with recent evidence showing that L1 has "clearly detectable" impacts on L2 word processing (Koda, 2005, p. 46) and is a primary source of differences among L2 learners (see reviews by Ganschow & Sparks, 2001; Sparks, 1995). Additional variance in predicting L2 spelling might also be explained by the orthographic distance and orthographic depth between the L1 and the L2. Ellis (2002) has speculated that differences in orthographic transparency are important for the rate of acquisition in another language. Likewise, the orthographic depth of the L2 and the orthographic distance be-

tween the L1 and L2 may affect the rate at which L2 learners acquire spelling skills.

In their study with young ESL learners, Wade-Woolley and Siegel (1997) found that L2 spelling performance was unrelated to the learners' L1 skill and that reading skill was a more significant influence on the ESL learners' spelling accuracy than their L1 skill. In contrast, the results of the present research with older L2 learners showed that L1–L2 spelling skills were strongly correlated (.69). The results suggest that L1–L2 spelling skills are likely to be strongly related even in older L2 learners who had learned to spell (and read) their L1 several years earlier, a finding that supports long-term cross-linguistic transfer of phonological processing skills from L1 to the L2.

### *L2 Reading Comprehension*

The regression analyses demonstrated that among the L1 variables, the measure of L1 reading comprehension (Formal Reading Inventory) was the best predictor of L2 reading comprehension. The finding that L1 reading comprehension was predictive of L2 comprehension is consistent with findings by VanGelderen et al. (2004), who observed that L1 reading comprehension in the 8th grade made large contributions to L2 reading comprehension skills in the 10th grade. The present results extend their research by showing that L1 reading comprehension in elementary school from the 1st through 5th grade was a significant predictor of L2 reading comprehension skill several years later in 10th grade.

The findings show that L1 measures, such as reading comprehension, word decoding, receptive vocabulary, and listening comprehension, explained a small part of the variance (25%) in L2 reading comprehension. Thus, much of the variance in L2 reading comprehension must be explained by other factors. In other studies, researchers have found that L2 word decoding skills play an important role in L2 reading comprehension skills (e.g., see Fukink et al., 2005; Koda, 1998). In this investigation, analyses were also conducted to determine whether first- and second-year L2 decoding skills would be predictive of L2 reading comprehension. The results revealed that when first-year L2 word decoding replaced the Woodcock Basic Skills Cluster as a predictor variable, L1 reading comprehension (Formal Reading Inventory) was still the best predictor of L2 reading comprehension. However, when second-year L2 word decoding replaced first-year L2 word decoding in the analysis, L2 word decoding was the best predictor and explained 39% of the variance ( $\beta = .62$ ) in L2 reading comprehension. This might have been expected because L2 word decoding was administered at the same time as the L2 reading comprehension measure, that is, at the end of the second-year L2 course. Nonetheless, the finding suggests that L2 word decoding explains a substantial part of the variance in L2 reading comprehension and accounts for more of the variance than either L1 reading comprehension skills or L1 word decoding skills. This corroborates studies reviewed by Koda (2005), who concluded that strong decoding skills are a prerequisite for efficient L2 comprehension. The results also support research that has shown that word decoding and other skills related to phonological processing (e.g., spelling) are the primary characteristics that distinguish between good and poor L2 learners (e.g., see Ganschow & Sparks, 2001; Sparks, 1995).

Despite the importance of L2 word decoding skills for L2 reading comprehension, decoding explained less than half of the

variance in L2 reading comprehension. Moreover, L1 language proficiency variables (e.g., L1 receptive vocabulary, L1 listening comprehension) did not explain significant additional variance in L2 reading comprehension. L2 researchers contend that oral proficiency in the L2 becomes more important for L2 reading comprehension as students become more proficient decoders and begin to read more difficult L2 text (Cummins, 1986; Nation, 2001). VanGelderen et al. (2004) found that L2 vocabulary knowledge significantly predicted L2 reading comprehension. In another study, Proctor et al. (2005) cited evidence that showed that the most important indicator of L2 oral proficiency may be L2 vocabulary knowledge, which is important for comprehension of both spoken and written language. In their study with fourth-grade ESL learners, they found that although L2 word decoding skills are important for L2 reading comprehension, word decoding played a less predictive role in L2 reading comprehension than did oral language proficiency and that L2 vocabulary knowledge played a crucial role in improving L2 reading comprehension. Other researchers have verified that the role of L2 vocabulary knowledge becomes more influential among adolescent and adult L2 learners (e.g., see Alderson, 1984; Laufer, 1997).

The aforementioned findings about L2 word decoding and L2 proficiency, especially L2 vocabulary knowledge, suggest that some L2 learners in the United States who do not begin to study an L2 until high school may experience difficulties developing their L2 reading comprehension skills. In the course of reading development in the L1, students read more difficult text as their decoding skills improve. As they read, they enhance their vocabulary and are exposed to increasingly difficult grammatical knowledge and decontextualized language, which also improves comprehension. In high school L2 courses, however, reading is both a mechanism by which instruction is delivered and a target goal of the L2 course (Proctor et al., 2005). Indeed, much of the instruction in high school L2 classrooms is conducted in the students' L1 because students are not yet competent in either the written or oral aspects of the L2. Coady (1997, p. 229) has identified what he called the beginner's paradox, which asks the question, "How can they learn enough words to learn vocabulary through extensive reading when they do not know enough words to read well?" L2 educators have rarely focused on teaching and assessing L2 word decoding skills as a prerequisite for reading L2 text (Koda, 2005); however, if students cannot decode L2 words well for reading, then it is unlikely that they will read very much or that their L2 classroom teachers will require them to read increasingly difficult L2 text. Proctor et al. (2005) cited evidence that indicates that adult L2 reading is similar to L1 reading comprehension processes as L2 word and grammar knowledge improve. However, it is unlikely that high school students who attempt to add an L2 in high school courses primarily as one of several academic subjects will become proficient in L2 reading comprehension if they do not acquire adequate L2 word decoding skills and do not read increasingly difficult text as an integral and ongoing part of their L2 instruction.

### *Limitations and Implications*

The present study is unique in several ways. In particular, the participants were followed over 10 years so that the possibility of long-term cross-linguistic transfer of L1 reading skills to L2 reading could be examined. Also, the participants learning an L2 were

high school students who were already proficient in the oral and written aspects of their L1 and generally were not studying the L2 to become bilingual but instead to fulfill an academic requirement. However, the study also has limitations that restrict generalizing the findings. For example, the small sample size limits the power of the statistical analyses. In addition, the use of nonvalidated measures for assessing L2 word decoding, spelling, and reading comprehension was necessary because standardized instruments for measuring these skills in an L2 are unavailable. Attempts were made to construct L2 assessments that closely resembled the L1 measures of this research; for example, on both the L1 and L2 reading comprehension tests, the student read the text silently and answered multiple-choice comprehension questions. Although the internal consistency of the L2 measures was checked, their construct or criterion-related validity was not determined. Thus, it is possible that higher scores on any one of the L2 measures, with the other two scores held constant, would not necessarily result in higher L2 proficiency in L2 reading. Also, Koda (2005) has proposed that for L2 reading comprehension, one type of assessment task, for example, multiple-choice items, cannot measure all of the skills necessary for successful comprehension. In addition, the participants studied three different L2s, each of which has a different orthography, and their scores were combined in the analyses. Though the three L2s were alphabetic orthographies, Koda has cautioned that "transferred skills [from L1 to L2] continuously undergo adjustments to accommodate L2 orthographic peculiarities" (Koda, 2005, p. 246). Therefore, combining the three different L2 groups may have served to blur unique distinctions between L1-L2 decoding, spelling, and reading comprehension in the three L2s.

Nonetheless, there are several ways in which the study contributes to both the L1 and L2 reading literature. First, mastery of L1 decoding skills early in the primary school years may be beneficial for students who attempt to learn an L2 in high school. Second, direct and explicit teaching of the phonology and orthography of the L2 to students may be beneficial in learning to read and spell the L2, especially if the L1 was mastered several years earlier. Likewise, direct and explicit teaching of the grammar of the L2 may be beneficial for comprehending an L2, especially if there are distinct differences between syntactic processing requirements of the L1 and L2. Third, after learning to decode the L2, new L2 learners may benefit from reading as much L2 text as possible because they would be more likely to increase their fluency, acquire the vocabulary and grammar of the L2, and learn the background knowledge they will need to comprehend the L2. Finally, L2 educators and researchers can collaborate to study further the importance of decoding skills for mastery of L2 reading.

# The Mnemonic Value of Orthography for Vocabulary Learning

Julie Rosenthal and Linnea C. Ehri  
Graduate Center of the City University of New York

In 2 experiments, the authors examined whether spellings improve students' memory for pronunciations and meanings of new vocabulary words. Lower socioeconomic status minority 2nd graders ( $M = 7$  years 7 months;  $n = 20$ ) and 5th graders ( $M = 10$  years 11 months;  $n = 32$ ) were taught 2 sets of unfamiliar nouns and their meanings over several learning trials. The words were defined, depicted, and embedded in sentences. During study periods, students were shown written forms of 1 set but not the other set. Spellings were not present during word recall. Results of analyses of variance showed that spellings enhanced memory for pronunciations and meanings compared to no spellings ( $ps < .01$ ). Better readers and spellers increasingly outdistanced poorer readers and spellers in remembering pronunciations over trials when spellings accompanied learning ( $p < .05$ ), suggesting a Matthew effect. An explanation is that spellings activated graphophonemic connections to better secure pronunciations and meanings in memory. Results indicate that orthographic knowledge benefited vocabulary learning and diminished dependence on phonological memory. Instructional implications are that teachers should include written words as part of vocabulary instruction and that students should pronounce spellings as well as determine meanings when they encounter new vocabulary words.

**Keywords:** vocabulary learning, orthographic memory, phonological working memory, spelling, vocabulary instruction

Vocabulary knowledge is central to successful reading comprehension and academic achievement (Beck & McKeown, 1999; National Reading Panel, 2000). Children's vocabularies grow rapidly during the school years. However, the variation in vocabulary growth among children is great. One factor contributing to this variation is the well-documented disparity between vocabularies of advantaged and disadvantaged populations (Chall, Jacobs, & Baldwin, 1990; Hart & Risley, 1995; Snow, Burns, & Griffin, 1998). Findings reveal that children who come to school with limited vocabularies never catch up to their higher quartile peers (Biemiller, 2001). In fact, students who are below average in their vocabularies and reading ability experience a reading slump in Grade 4, when subject matter texts become increasingly abstract and complex. This slump worsens in seventh grade and beyond, when knowledge of word meanings becomes crucial to academic success (Chall et al., 1990). Thus, there is a clear need for better methods of building students' vocabularies in school. The purpose of the present study was to examine the contribution of ortho-

graphic knowledge—that is, exposure to the spellings of words—in facilitating students' vocabulary growth.

Vocabulary knowledge consists of the stock of words known by a person. Word knowledge involves multiple identities and dimensions (Nagy & Scott, 2000): a phonological identity including constituent phonemes and how the word is pronounced; one or more syntactic identities specifying the word's form class and function in sentences; one or more semantic identities, or meanings of the word in various contexts; and an orthographic identity, or the word's spelling. This knowledge may also include morphological information distinguishing roots and affixes or compound parts of multimorphemic words. It may include other words that typically co-occur with the word or are associated with it. Its meaning may include not only referential elements that are visual and verbal but also affective elements. Word knowledge may range from partial to complete, or it may involve misconceptions. It may support only recognizing word meanings, or it may enable productive use of the word. A vocabulary learning task may include a word's formal definition, its use in various sentence contexts, or a picture of its referent. It may require learning a new concept or learning a new label for a known concept. Vocabulary learning may result from explicit instruction by a teacher, or it may emerge from incidental encounters with unknown words. One may learn words and their meanings by hearing them spoken or by reading them. However, simply learning to decode or to spell words or to read words by sight when the meanings of those words are already familiar or when meanings are lacking (i.e., nonwords) is not considered part of vocabulary learning.

Although there are multiple dimensions to vocabulary knowledge, its essence involves remembering the pronunciations of words and their meanings. According to Gathercole (2006) and Gathercole and Baddeley (1993), being able to repeat a new

Julie Rosenthal and Linnea C. Ehri, Program in Educational Psychology, Graduate Center of the City University of New York.

The study was funded in part by the Jeanne S. Chall Research Fellowship from the International Reading Association and by the Mario Capelloni Dissertation Fellowship from the Graduate Center of the City University of New York. We thank Hollis Scarborough and David Rindskopf for their helpful comments and suggestions. We are grateful to students and staff at the public elementary school in New Jersey where this study was conducted.

Correspondence concerning this article should be addressed to Julie Rosenthal, who is now at the Department of Elementary and Early Childhood Education, William Paterson University of New Jersey, 300 Pompton Road, Wayne, NJ 07470. E-mail: rosenthalj@wpunj.edu

word's pronunciation accurately depends on having good phonological short-term working memory and is critical for explaining how people, especially young children, are able to remember spoken words. When words are repeated, they become represented temporarily in a phonological loop in working memory until they can be transferred to a more permanent lexical-semantic memory system. Phonological working memory is assessed with a nonword repetition task. In one study, Gathercole and Baddeley (1989) showed that phonological working memory capacity predicted the ease with which children between the ages of 4 and 6 years learned novel phonological blends as names for known objects, but it did not predict learning when the names were familiar. However, among 8-year-olds, nonword repetition was much less predictive of vocabulary scores. Other studies have confirmed that individual differences in phonological working memory underlie vocabulary acquisition, particularly in young children (Gathercole, 2006). The purpose of the present study was to examine whether exposure to the spellings of words might impact the formation of phonological representations of new vocabulary words in memory.

Research on vocabulary acquisition has been extensive (see Beck & McKeown, 1991, 1999; Biemiller, 2006; Nagy & Scott, 2000). One of the puzzles has been to explain vocabulary growth. Students acquire knowledge of many more words than they are taught explicitly by teachers or look up in dictionaries. The consensus is that much of this knowledge is acquired incidentally through exposure to words in speech or print. Many vocabulary studies conducted with students beyond the early years, after they have learned to read, have examined word learning through print exposure (Beck & McKeown, 1991; Swanborn & deGlopper, 1999). However, few, if any, studies to date have examined experimentally whether seeing the spellings of words contributes to vocabulary learning. The prevailing view appears to be that when new vocabulary words are encountered in print, they are transformed into pronunciations, which are then stored in memory along with word meanings. The written form is not viewed as making any special contribution to memory beyond its spoken form. Gathercole and Baddeley (1993) did not include orthographic representations in their model.

Examination of recommendations by vocabulary instruction experts reveals little, if any, explicit incorporation of print into instruction. Blachowicz and Fisher (2004) recommended that teachers expand students' vocabularies by reading text aloud to their classes, thereby providing access to words too difficult for students to read independently. They suggested that teachers stop at difficult words, provide definitions, reread the text to "cement" new word meanings, and have students "act out" the meanings of new words. However, they did not suggest displaying the spellings of new words. Biemiller (2004) also recommended that teachers read texts aloud to students in kindergarten through Grade 2 to build their vocabularies. He recommended using books with more sophisticated vocabulary and explaining harder words during rereadings, but nowhere did he mention exposing students to spellings of words. Trelease (2006), in his very popular *The Read Aloud Handbook*, stated that the single most effective way to build students' vocabularies is by reading aloud to them, but he, too, never suggested showing word spellings. Beck, McKeown, and Kucan (2002; Beck & McKeown, 2007) recommended multiple steps for teaching new words from trade books after teachers have read them aloud to students: (a) review the more difficult words

and where they occurred in the story and explain their meanings, (b) have children repeat the words aloud to build their phonological representations and orally present the words in sentences, (c) have children construct additional sentences, and (d) then have them say the words aloud again. At the very end, the spellings of the words are finally shown when the words are added to a word wall in the classroom.

Whereas orthography has been overlooked in studies of vocabulary acquisition, the meanings of words have been overlooked in research on the acquisition of decoding skill. In this work, the primary interest has been on the formation of connections between orthography and phonology that enable children to decode and spell written words rather than on the formation of semantic connections. In fact, decoding researchers regard the ability to read nonwords, which have no meaning, as the best way to assess readers' skill in reading unfamiliar (i.e., new vocabulary) words (Ehri, 1991; Gough & Tunmer, 1986; Rack, Snowling, & Olson, 1992; Share, 1995). As a result, the vocabulary and decoding research domains overlap very little. One purpose of the present study was to bring the two closer together by examining whether and how orthography contributes to the acquisition of words and their meanings.

In the present study, vocabulary learning consisted of explicitly teaching children the spoken forms and meanings of several monomorphemic nouns. The words were pronounced, defined, and embedded in sentences, and drawings of referents were displayed on flash cards to teach pronunciations, syntactic roles, meanings, relationships to other words, and links to world knowledge. In addition, spellings of the words appeared on the cards in one condition, while spellings were not seen in the other condition. We assessed vocabulary learning by evaluating whether children could recall pronunciations of the words when prompted with their meanings and could recall their meanings when they heard the words spoken.

There are various reasons to expect that exposure to the written forms of unfamiliar words might help students learn and remember them better. According to Ehri's (1992, 1999, 2005) connectionist theory, knowledge of the orthographic writing system provides a powerful mnemonic device enabling readers to secure the spellings of specific words to their pronunciations in memory. For connections to be formed, readers must be able to distinguish phonemes in spoken words, know how graphemes symbolize those phonemes systematically in the writing system, and compute these grapho-phonemic connections when they see spellings and speak or hear pronunciations of the words. As a result of this processing, spellings of the words become bonded to their pronunciations and meanings, and the amalgam is stored in memory. Having words stored in memory precludes the need to apply sounding out, analogy, or guessing strategies to read the words. On seeing familiar words, readers can recognize them from memory (by sight). Others have proposed similar theories (Rack, Hulme, Snowling, & Wightman, 1994; Perfetti, 1992; Share, 1995, 1999).

Ehri and Wilce (1979) showed that spellings function as a mnemonic device enabling readers to retain pronunciations of nonwords in memory. An everyday example of this function is when one hears an unfamiliar personal name, examines how it is spelled, and remembers it better as a result. In Ehri and Wilce's study, first and second graders were given several trials to learn four spoken nonsense syllables (e.g., *jad*, *sim*, *des*, *fug*). The

conditions of learning varied across groups. The experimental group was shown written forms of the words during study periods but not during recall trials. Several control groups were included. The students in these groups rehearsed the spoken forms of nonwords extra times in various ways but did not see their spellings. Across all comparisons, students recalled the nonwords significantly better when they had been exposed to spellings during study periods than when they had not. The effect of spelling aids on memory was stronger for students with larger lexicons of printed words, which indicates that better orthographic knowledge strengthened the benefit of spellings. Results were interpreted to support the idea that spellings facilitate word learning because they activate the formation of orthographic images symbolizing and securing the words' pronunciations in memory. However, because nonwords were used, findings provided no information about the learning of new words that included meanings.

The purpose of the present study was to adapt the word-learning procedures used by Ehri and Wilce (1979) to study vocabulary learning. The question of interest was whether elementary students would better learn and remember the pronunciations and meanings of new words when they were exposed to spellings of the words than when they practiced only spoken forms of the words. A paired associate learning task was adopted to study these processes in a controlled way. In a repeated measures, counterbalanced design with random assignment, second and fifth graders were taught two sets of low-frequency nouns and their meanings. For one set, they saw spellings of the words during study periods. For the other set, they did not see the spellings. Instead, they received extra practice hearing and pronouncing the words. Use of this control for exposure to spellings was based on the prevailing view of print in vocabulary learning, that spellings of new words are transformed into pronunciations, which are the forms associated with meanings in memory. It is important to note that when recall of pronunciations was tested, written words were never present, so children had to retrieve them from memory.

This design was used to test several hypotheses. On the basis of grapheme-phoneme connectionist theories, we reasoned that spelling exposure should facilitate learning pronunciations, because spellings better secure pronunciations in memory. We also expected that word meanings would be learned more quickly if spellings secured pronunciations in memory earlier during the learning trials. Regarding grade-level differences, we reasoned that the benefit of orthography might be diminished in fifth graders compared to second graders because older students possess larger vocabularies, more extensive memory for the phonological forms of words, and greater decoding proficiency.

Extensive research on vocabulary learning has clarified factors that influence the ease of learning word meanings. Carey (1978) observed "fast mapping" in preschool children, who could very quickly learn the referents for new words but took longer to acquire a more complete understanding of their meanings. Vocabulary learning is faster when concrete images of word meanings can be represented in memory and when words are defined verbally and experienced in multiple sentence contexts, so that their meanings are connected to other word meanings, becoming embedded in a speaker's web of linguistic and world knowledge, as portrayed by dual coding theory (Sadoski, 2005). The present study included pictures, definitions, and sentences as part of vocabulary learning to support the acquisition of word meanings.

Many vocabulary studies have examined growth in receptive knowledge, most often measured by multiple-choice tests (Senechal, 1997). However, language users need to know new vocabulary words well enough to incorporate them into their speech. The requirements for doing this are more stringent than the requirements for simply recognizing words because the latter process may be aided by morphological information, verbal context, or guessing (Baumann & Kameenui, 1991). The present study was intended to examine whether seeing the spellings of new words strengthens growth in expressive vocabulary.

## EXPERIMENT 1: VOCABULARY LEARNING WITH SECOND GRADERS

### Method

#### *Participants*

In a mid-size city, 20 second graders were selected from a school where 58% of the students qualified for free or reduced-price lunch. Participants were those whose parents gave written consent, who were not receiving English language services, and who exhibited no cognitive or sensory impairments according to their teachers. There were 11 girls and 9 boys, of whom 15 were African American and 5 were Latin American, with a mean chronological age of 7 years 7 months, tested in the fall.

#### *Materials and Procedures*

##### *Literacy Assessment*

Several tests were administered. The purpose was to assess students' orthographic knowledge and vocabulary level.

*Reading words.* Graded lists of words on the Word Identification subtest of the Woodcock Reading Mastery Test—Revised (WRMT-R; Woodcock, 1987) were given to assess students' word-reading level. According to the manual, the reliability is .98.

*Reading and spelling nonwords.* Nonsense words were constructed from letters appearing in the new vocabulary words to be taught. Students read 15 consonant-vowel-consonant (CVC) nonwords and spelled 8 CVC nonwords containing short vowels. Examples are *pag*, *kem*, *hin*, *nol*, and *yud*. The split-half reliabilities in our sample were .89 (nonword reading) and .28 (nonword spelling). One reason for the lower value in the latter case is that there were only 8 nonwords, and at least 3 of these were misperceived as real words by some students (e.g., *hin* spelled *hen*).

*Vocabulary.* The Peabody Picture Vocabulary Test (PPVT-III; Dunn & Dunn, 1997) was administered to assess students' receptive vocabulary. According to the manual, reliabilities range from .91 to .94.

##### *Vocabulary Learning*

Two sets of six concrete, low-frequency CVC nouns served as the target vocabulary words, one set to be taught with spellings, the other set to be taught without spellings in a repeated measures design. We consulted several "rare words" Web sites to obtain the words: <http://hometown.aol.com/rlongman1/wordAO.html>, <http://www.islandnet.com/~egbird/dict/dict.htm>, and <http://phrontistery.info/>.

Teachers of the students were shown the words and agreed that their students were unlikely to know them. All but one word (*lad*) was rated as low frequency (i.e., occurring less than 11 times per million words) by Thorndike and Lorge (1972). Although *lad* was more frequent, Harris and Jacobson (1982) rated it as a fourth-grade-level word.

Words in each set began with a different consonant and included a different short vowel, except for short *a*, which appeared twice in each set. A core definition was constructed that included a close synonym for each word. These appear in Table 1. Some of the meanings were simplified. For example, *nib*, meaning the point of a pen, was taught as "a pen." The spelling of one word, *fete*, was regularized to *fet*. Five meaning-clarifying sentences were written for each word—for example,

A keg can hold many kinds of liquids. A keg is big and can hold a lot of water. A keg is usually made out of wood or plastic. A keg is big and round. Some people keep pickles in a keg.

Pictures depicting the meanings of the nouns were drawn on cards. One set of cards showed the written words beneath pictures, while the other set did not. Another set of cards showed only the written words.

At the start of the vocabulary learning tasks, procedures were explained and illustrated with an example. Children were told that they should learn the name and meaning of each picture because later they would be tested. The first trial was a study trial, when the words were introduced. Students were shown each picture, heard the word pronounced and embedded in a defining sentence, and repeated the word and sentence. All subsequent trials prompted their recall of pronunciations and meanings. Two types of prompted recall trials were interleaved during learning: a trial presenting all six pictures and testing memory for spoken words, followed by a trial presenting the six spoken words and testing memory for their definitions. The order of the words was varied across trials.

During pronunciation recall trials, each picture depicting the word was presented, and children were given 5 s to say the word. Feedback followed in which the experimenter continued to display the picture, spoke the word, and embedded it in one or two sentences. On Test Trial 1, the embedded sentence was the defining sentence. On subsequent trials, different meaning-elaborated sentences followed the defining sentence. If children misrecalled an item, they repeated the word and its defining sentence.

During meaning recall trials, each word was spoken, and children had 5 s to recall the definition. Feedback consisted of the experimenter providing the defining sentence. After the first test trial, feedback on each trial included a different meaning-elaborated sentence. Again, if children misrecalled a word's definition, they repeated the word and the defining sentence.

Oral definitions were scored as correct or incorrect. There were no instances of nearly correct responses because all of the words were concrete nouns that were close synonyms of familiar nouns and were included in the defining sentences. Students' responses were correct if they produced the more familiar synonym. For example, the word *cur* was defined as a homeless dog. Children had to produce the close synonym *dog* to be correct. Errors on this task were mostly recalling synonyms of other target words or no response.

Each student learned two sets of words. One set was taught by exposure to spellings of the words. However, no attention was drawn to the written words during the experiment, and the written words were never present when children recalled their spoken forms, so that any influence of spellings arose from students' memory for the spoken words. Exposure to spellings was limited to specific points during the study and test trials. Written words appeared beneath pictures of the nouns during the initial study trial. During test trials, after each attempt to recall the spoken word, the experimenter provided feedback by showing the written words beneath their pictures while saying the words and their sentences. Recall of the meanings of words was prompted by the

Table 1

*Mean Number of Second Graders Who Recalled Spoken Words and Meanings Correctly Per Trial During the First Five Learning Trials for Each Vocabulary Word as a Function of Whether Students Were Exposed to Spellings of the Words in Experiment 1*

Vocabulary word	Meaning	Recall spoken word		Recall meaning	
		Sp.	No sp.	Spell	No sp.
Tot	A small, young child	7.2	5.0	10.0	8.4
Hun	Someone who destroys things	6.6	5.2	9.6	9.6 <sup>a</sup>
Lad	A boy who works with horses	6.0	4.0	9.0	8.0
Sod	Wet, grassy ground	5.2	3.4	8.0	7.8
Pap	Soft, mushy food for babies	5.0	3.2	8.2	8.8 <sup>a</sup>
Cur	A homeless dog	5.0	2.6	9.6	8.4
Yag	Fake jewelry	4.6	2.6	8.4	7.6
Fet	A big, fun party	4.2	2.4	8.8	6.8
Nib	A pen	4.0	1.4	8.8	8.4
Gam	A family of whales	3.8	2.2	9.0	6.0
Keg	A barrel that holds water	3.6	1.8	8.4	8.2
Rig	A big, strong truck	3.2	1.6	8.8	6.4

*Note.* The maximum number of students who recalled a word correctly was 10. Sp. = spelling.

<sup>a</sup> There were two exceptions to the general pattern of superior learning when spellings were seen compared with when spellings were not seen, both involving the recall of word meanings.

experimenter saying the words while showing their spellings for less than 1 s as the word was spoken.

In the spelling-absent condition, no written words accompanied spoken words, sentences, or pictures. Instead, the experimenter pronounced the words additional times, and children repeated the words additional times to equate stimulus exposures across the two conditions. In fact, the total number of oral exposures to the words in the spelling-absent condition was greater than the total number of exposures (written plus oral) in the spelling-present condition. Children heard and repeated each word twice during every feedback trial after attempting to recall its pronunciation, and they heard each word twice rather than once on test trials as they attempted to recall its definition.

Children received a minimum of six and maximum of nine trials to learn pronunciations and definitions in each condition. If they reached a criterion of three perfect consecutive trials on both tasks before nine trials, then learning was terminated, provided that the minimum of six trials had been completed. This meant that students in the spelling-present condition heard, spoke, or saw each word between 47 and 68 times, and students in the spelling-absent condition heard or spoke each word 53 to 77 times, depending on the number of learning trials. The order of treatment condition (written words present or absent) and the word set used in each treatment (Set 1 or Set 2) were counterbalanced. Children were randomly assigned to condition, with 5 children receiving each possible order and set.

### *Vocabulary Posttests*

Memory for the newly learned words was tested after a 1-day delay via three experimenter-devised tasks given in the order listed. Internal consistency reliabilities were estimated from our sample. In the word production task, students listened to the core definition of each word and recalled its pronunciation. The reliabilities were .56 in both the spelling and the no-spelling conditions. In the spelling production task, students heard each word and wrote its spelling. The reliabilities were .57 in the spelling condition and .60 in the no-spelling condition. In the recognition matching task, students were shown the six vocabulary words written across the top of a page, followed by 12 meaning-elaborated sentences that were heard during the word-learning task. Target words were replaced by blank spaces. The words and sentences were read aloud by the experimenter, and children chose the words that best completed the sentences. The reliabilities were .70 in the spelling condition and .41 in the no-spelling condition.

All testing was conducted with individual children over 3 consecutive days in 40-min sessions. On Day 1, children were taught one set of words in one of the conditions. On Day 2, they were posttested on their memory for Day 1 words and meanings and taught the second set of words in the other condition. On Day 3, they were tested on their memory for Day 2 words and then administered the tests of vocabulary and literacy.

## Results and Discussion

Performance on the literacy tests revealed that, on average, the second graders were reading at grade level on the WRMT-R Word Identification subtest ( $M = 2.2$  grade-equivalent score,  $SD = 0.68$ ). Also, they read and spelled about half of the CVC nonwords

correctly ( $M = 55\%$  read,  $M = 53\%$  spelled). However, their performance on the PPVT vocabulary test was substantially below national norms, with a mean standard score of 87.5 ( $SD = 11.0$ ). Scores of the Latin American students were very similar to scores of the African American students. These findings indicate that second graders in the present study possessed average word reading skills but below average vocabularies.

A preliminary analysis of vocabulary learning was conducted to evaluate the effects of the two control variables resulting from the counterbalanced design: word set (i.e., Set 1 vs. 2) and learning order (i.e., words with spellings learned before vs. after the words without spellings). The dependent measure was the difference between the number of trials to reach criterion in learning words with spellings and the number without spellings (i.e., criterion equaled three perfect successive trials). Two-way analyses of variance (ANOVAs) were conducted with word set and learning order as the between-subjects, independent variables. In one ANOVA, the dependent measure was the difference in pronunciation recall in the with- versus without-spellings conditions. In the second ANOVA, the dependent measure was the difference in definition recall in the with- versus without-spellings conditions. No significant main effects or interactions involving word set or task order were detected in either analysis (all  $ps > .05$ ). Hence, these control variables were dropped from further analyses. These ANOVAs also included a test of the intercept term, which is conducted as part of an ANOVA by the SPSS statistical program. When the dependent measure is a difference score, the intercept test indicates whether the mean difference is significantly different from zero. In the present analyses, the intercept tests were significant, favoring the spelling over the no-spelling condition,  $F(1, 16) = 8.53$ ,  $p < .01$ , for pronunciation recall;  $F(1, 16) = 18.44$ ,  $p < .01$ , for definition recall.

The next analyses examined the number of trials to criterion that students required to learn pronunciations and definitions. The independent variable was a repeated measure comparing the presence versus absence of spelling aids. Mean performance and test statistics are reported in Table 2. Paired-sample  $t$  tests revealed that learning of both pronunciations and meanings was significantly better with than without spellings. On the basis of Cohen's (1988) rule of thumb (i.e., .20 is a small effect, .50 is a moderate effect, and .80 is a large effect), effect sizes were moderate to large (see Table 2). The percentages of students reaching criterion in the two treatment conditions were quite disparate as well and favored spelling aids over no aids (see Table 2). These findings show that exposure to written words exerted a powerful effect on learning the pronunciations of new vocabulary words and their definitions.

To compare growth from trial to trial in the two tasks and conditions, we conducted an ANOVA with learning task (pronunciations vs. definitions), spelling condition (present vs. absent), and trials (Trials 1 through 5) as the independent variables. All were repeated measures. The dependent variable was correct recall. Results revealed significant main effects of task,  $F(1, 19) = 217.16$ ,  $p < .01$ ; spellings,  $F(1, 19) = 23.70$ ,  $p < .01$ ; and trials,  $F(4, 16) = 41.01$ ,  $p < .01$ , as well as significant interactions between task and spelling condition,  $F(1, 19) = 12.64$ ,  $p < .01$ , and between task and trials,  $F(4, 16) = 13.47$ ,  $p < .01$ . The remaining interactions were not significant (both  $ps > .05$ ). Mean performance is shown in Figure 1.

Table 2  
*Mean Performance Recalling Spoken Words and Meanings as a Function of Whether Students Were Exposed to the Spellings of Words in Experiment 1*

Tasks and measures	Spelling ( <i>n</i> = 20)	No spelling ( <i>n</i> = 20)	<i>t</i> (19)	Effect size <sup>a</sup> ( <i>d</i> )
Learning spoken words				
Trials to criterion (9 max)	7.9 (1.6)	8.7 (1.0)	3.11**	0.61
% reaching criterion	50%	15%		
Learning definitions				
Trials to criterion (9 max)	5.0 (1.8)	7.0 (2.3)	4.12**	0.98
% reaching criterion	100%	60%		
Posttests				
Recalling spoken words (6 max)	4.0 (1.5)	2.9 (1.5)	3.93**	0.73
Recalling spelling of words (6 max)	4.5 (1.5)	3.0 (1.7)	3.81**	0.94
Matching words to sentences (12 max)	11.5 (0.9)	10.8 (1.7)	1.93	0.54

Note. Standard deviations are in parentheses.

<sup>a</sup> Calculation of effect size: difference between means divided by pooled standard deviation.

\*\*  $p < .01$ .

Regarding the main effect of task, as is apparent in Figure 1, word definitions were recalled more easily than pronunciations of words across trials. Regarding the interaction between task and trials, differences favoring definitions over pronunciations were huge during earlier trials and diminished as memory for the pronunciations improved. Regarding the main effect of spelling condition, as seen in Figure 1, both pronunciations and definitions were learned more quickly with spelling aids than without aids. Regarding the interaction between task and spelling condition, the advantage of seeing spellings over not seeing them was greater when students learned pronunciations of words than when they learned definitions. From these findings, we conclude that the presence of written words during study and feedback periods helped children learn new vocabulary words and their definitions. Moreover, remembering pronunciations of the new words was harder than remembering their definitions.

To determine whether the benefit of spelling exposure held across words as well as students, we calculated the mean number of correct responses over the first five trials for each student learning each word and averaged these values. Comparison of means shown in Table 1 reveals that 100% of the spoken words

and 83% of the definitions showed the pattern favoring superior learning with spelling aids compared to no spelling aids. These findings confirm that the benefit of seeing spellings generalized across both words and students, and it held for learning meanings and pronunciations.

We gave posttests 1 day later to assess whether students remembered the spoken words and meanings after a delay. Mean performance and test statistics are reported in Table 2. Paired-sample *t* tests revealed that students recalled the spoken words significantly better in the spelling than in the no-spelling condition ( $M = 67\%$  vs.  $48\%$  correct). Also, students wrote the words more accurately if they had seen spellings than if they had not ( $M = 75\%$  vs.  $50\%$  correct), which indicates that the spellings had been stored in memory. These findings show that the benefit of spellings for vocabulary learning persisted at least 1 day later. On the measure of performance matching words to their sentences, the difference favoring spellings over no spellings fell short of statistical significance ( $p > .05$ ), possibly because of ceiling effects reflecting almost perfect recognition of word meanings ( $M = 90\%$  to  $96\%$  correct).

We calculated correlation coefficients to determine whether students' performance in our laboratory word learning tasks was related to their vocabulary and literacy skills, as assessed by tests of word and nonword reading, nonword spelling, and PPVT receptive vocabulary. The laboratory measures of vocabulary learning were the mean numbers of pronunciations and definitions correctly recalled on Trials 1–5 in the spelling and no-spelling conditions. Findings revealed that the WRMT–R word reading test correlated strongly with recall of pronunciations in the spelling-present condition ( $r = .67, p < .01$ ) and the no-spelling condition ( $r = .55, p < .05$ ). The nonword reading test showed the same pattern ( $r = .49, p < .05$ , and  $r = .47, p < .05$ , respectively). The PPVT vocabulary test correlated significantly with recall of definitions in the spelling-present condition ( $r = .48, p < .05$ ) but fell short of significance in the spelling-absent condition ( $r = .40, .05 < p < .10$ ). None of the other correlations reached statistical significance (all  $ps > .05$ ). Findings suggest that the ability to remember the pronunciations of new vocabulary words, whether

Figure 1. Mean number of pronunciations recalled in the spelling condition (Pron-Sp) and in the no-spelling condition (Pron-NoSp), and mean number of definitions recalled in the spelling condition (Def-Sp) and in the no-spelling condition (Def-NoSp) over five learning trials in Experiment 1.

learned with or without spelling aids, is influenced by students' orthographic knowledge.

## EXPERIMENT 2: VOCABULARY LEARNING WITH FIFTH GRADERS

Experiment 2 was conducted to replicate and extend results of the first experiment. The participants were fifth rather than second graders. Ten multisyllabic words, rather than six monosyllable words, were taught in each condition (i.e., with vs. without spelling aids). The sample size was enlarged from 20 to 32 participants. Posttests were expanded to include transfer tasks.

One question of interest was whether exposure to spellings would help older students learn pronunciations and meanings of the words better than no exposure. Because older students are more proficient decoders and possess greater knowledge of written and spoken words, they may anticipate spontaneously how unfamiliar spoken words are spelled when they hear and practice them, even without spelling aids (Stuart & Coltheart, 1988). If so, exposure to spellings may exert a smaller influence on their vocabulary learning than on younger students' learning. Alternatively, the opposite effect might occur. According to Ehri and Wilce (1979), having greater knowledge of the orthographic system should facilitate memory for written words, particularly if the words are multisyllabic and, hence, harder to remember.

### Method

#### Participants

The participants were 32 fifth graders from the same school as those in Experiment 1. The sample included 31 African Americans, 1 Latin American, 18 girls, and 14 boys whose parents had given written consent to participate. Mean chronological age was 10 years 11 months. Participants were tested in the spring. Teachers verified that no one exhibited any cognitive or sensory impairment or received English language services.

#### Materials and Procedures

##### Literacy Assessment

Several tests were given. The purpose was to assess students' vocabulary and literacy skills.

*Reading words.* Graded lists, each of which had 20 words, from second through eighth grade, were taken from the Boder Test of Word Reading (Boder & Jarrico, 1982). Students were allowed 5 s to read each word. Reading was stopped when students were unable to read more than 6 words in a list. The split-half reliability in our sample was .98. Conversion of scores to grade-equivalent values was based on list-level performance rather than national norms, which are not provided in the test manual.

*Test of Word Reading Efficiency (TOWRE) Test of Phonemic Decoding Efficiency (Torgesen, Wagner, & Rashotte, 1999).* Children were given 45 s to read as many nonwords as possible from a list of increasingly difficult items. The score was based on the number pronounced correctly. According to the manual, test-retest reliability is .83.

*Ganske Spelling Inventory (Ganske, 2000).* Twenty progressively more difficult words were pronounced and embedded in

sentences. Children repeated and wrote the words. The task was terminated if fewer than two words in a set of five were correct. Scores were based on the number correctly spelled. The split-half reliability in our sample was .90.

*PPVT-III.* Students were administered the PPVT-III.

##### Vocabulary Learning

Two sets of 10 concrete, multisyllabic, low-frequency nouns were taught. The same rare word Web sites were consulted to locate the words as in Study 1. Teachers judged that their students would not know them. Also, most of the words proved unfamiliar to a sample of graduate students. The words were rated as occurring fewer than four times per million words, with 16 of the words so infrequent that they were not rated (Thorndike & Lorge, 1972).

Words within each of the two sets began with a different consonant. Each set consisted of 5 two-syllable and 5 three-syllable words. The words and core definitions appear in Table 3. Three definitions were simplified or made concrete to be more readily understood, more easily depicted, or more appropriate for fifth-grade learners (i.e., *koomkie*, meaning a female elephant in heat; *frenulum*, meaning the membrane that holds the tongue back from extending too far; and *juggernaut*, meaning a large, overpowering force or object; see Table 3 for the simplified definitions that were taught). Four meaning-clarifying sentences were constructed for each word. The format of the materials and the procedures used to teach and test recall of the words and meanings were the same as in Experiment 1, except that students were given a minimum of five and a maximum of eight trials to learn the words and their meanings. This meant that in the spelling-present condition, students heard, spoke, or saw each word 40 to 61 times, and students in the spelling-absent condition heard or spoke each word 45 to 69 times, depending on the number of learning trials. The order of the treatment (i.e., whether students learned words with or without spellings first) and the word set taught in each treatment were counterbalanced. Children were randomly assigned to condition, with 8 children receiving each possible order and set.

##### Vocabulary Posttests

Memory for spoken words and meanings was tested after a 1-day delay with five experimenter-devised tasks that were given in the following order. Internal consistency reliabilities were estimated.

*Oral cloze task.* In this transfer task, students' ability to recall the spoken forms of target words and fit them in appropriate sentence contexts was assessed. The experimenter read orally 20 new sentences that included the words and clearly expressed their meanings. Students listened to each sentence with the target word omitted and pronounced the missing word. The reliabilities were .67 in the spelling condition and .60 in the no-spelling condition.

*Recall spoken words.* Students were shown the same pictures used during training but without any written words and recalled the words. The reliabilities were .72 in the spelling condition and .67 in the no-spelling condition.

*Recall definitions of words.* Students heard each word pronounced and provided its definition. No written words were present. Students performed almost perfectly, making it impossible to estimate this test's reliability with our data.

Table 3

*Mean Number of Fifth Graders Who Recalled Each Spoken Word Correctly Per Trial During the First Five Learning Trials and Who Recalled Each Meaning Correctly Per Trial During the First Three Learning Trials as a Function of Whether Students Were Exposed to Spellings of the Words in Experiment 2*

Vocabulary words and meanings	Recall spoken		Recall meaning	
	Sp.	No sp.	Sp.	No sp.
Barrow—a small hill	13.2	10.6	15.7	12.7
Juggernaut—a large truck	11.0	6.2	14.7 <sup>a</sup>	16.0 <sup>a</sup>
Wimple—what nuns wear on their heads	10.6	6.8	12.3 <sup>a</sup>	13.7 <sup>a</sup>
Mullock—a pile of trash	9.8	7.0	13.0	11.0
Tandem—a horse-drawn carriage	9.8	3.8	14.0	12.7
Fribble—a foolish, shallow person	9.8	2.8	13.0	11.0
Potlatch—a Native American festival where the chief gives out gifts	9.6	9.4	14.0	13.0
Dobson—a bug that is a kind of beetle	9.4	6.2	15.0	11.0
Muleta—a red cape	9.2	5.2	15.0	13.0
Koomkie—a female elephant that attracts male elephants	9.2	4.4	15.7	13.7
Vibrissa—the whiskers on a cat	9.2	3.4	15.3	14.7
Gangrel—a homeless person	8.8	8.6	15.3 <sup>a</sup>	15.3 <sup>a</sup>
Tamarack—a big tree found all over America	8.0	2.2	13.3	10.3
Chigger—a kind of bug that eats the blood of animals and people	7.8	4.4	14.3	13.7
Hicatee—a kind of turtle that lives in the water	7.4	5.6	14.0	12.7
Laburnum—a small tree with bright yellow flowers	6.8	3.0	14.0	11.3
Kerfuffle—a fuss or fight	6.2	4.0	14.7	12.0
Proboscis—a really big nose	6.0	5.2	12.7	10.7
Frenulum—a tongue	5.8	2.0	14.7	10.7
Scrivello—the tusks on an elephant	4.4	2.2	12.7	9.0

*Note.* The maximum number of students who recalled a word correctly was 16. Sp. = spelling.

<sup>a</sup> There were three exceptions to the general pattern of superior learning when spellings were seen compared with when spellings were not seen, all involving the recall of word meanings.

*Recognize meanings of words.* In this transfer task, students were shown four new pictures not previously seen during training, a target word was spoken by the tester, and students selected the picture that best illustrated the word. The foils consisted of unseen pictures of other target words. Each picture appeared multiple times, once as a target, and other times as a foil. Students performed almost perfectly, making it impossible to estimate this test's reliability with our data.

*Spell words.* Students heard each target word pronounced, repeated it, and wrote its spelling. The reliabilities were .81 in the spelling condition and .61 in the no-spelling condition.

All testing was conducted with individual children over 3 consecutive days and followed the same schedule used in Experiment 1 (see above). Each session lasted about 40 min.

## Results and Discussion

Performance on the Boder Test of Word Reading revealed a bimodal distribution, which provided the basis for dividing students by orthographic knowledge into a lower level group ( $n = 18$ ), who read fewer than 93 words, and a higher level group ( $n = 14$ ), who read more than 106 words. The lower group's mean performance was below grade level, whereas the higher group's mean performance was above grade level (see Table 4). Characteristics and mean performance of the two groups on the other tests are reported in Table 4. Results of  $t$  tests revealed that the groups did not differ significantly in receptive vocabulary, which was

somewhat below the national average, but they clearly differed in their nonword decoding and spelling skills. Correlation coefficients revealed strong relationships among the measures of word and nonword reading and spelling, with correlations ranging from .69 to .82 ( $ps < .01$ ). These findings show that higher and lower level readers differed in their knowledge of the orthographic system but not in their receptive vocabulary knowledge.

We conducted a preliminary analysis of vocabulary learning to evaluate the effects of two control variables resulting from the counterbalanced design: word set (i.e., Set 1 vs. 2) and learning order (i.e., spelling present condition completed first vs. second). The dependent measure was the difference between the number of trials to criterion to learn words with spellings and the number of trials to learn words without spellings (i.e., criterion equaled three perfect successive trials). Two-way ANOVAs were conducted with word set and learning order as the between-subjects, independent variables. No significant main effects or interactions involving word set or task order were detected (all  $ps > .05$ ). Hence, these control variables were dropped from further analyses. However, results revealed a significant effect of intercept, indicating that the mean difference score was significantly greater than zero, favoring the spelling over the no-spelling condition,  $F(1, 28) = 19.55$ ,  $p < .01$ , for word recall;  $F(1, 28) = 33.56$ ,  $p < .01$ , for definition recall.

The next two analyses examined the numbers of trials to criterion that students required to learn pronunciations and definitions.

Table 4  
*Student Characteristics and Mean Performance on Literacy and Language Tests as a Function of Reader Level as Determined by the Boder Word Identification Test in Experiment 2*

Characteristics and measures	Reader level		<i>t</i> (30)
	Lower ( <i>n</i> = 18)	Higher ( <i>n</i> = 14)

The independent variables were spelling condition (present vs. absent, within subject) and reader level (higher vs. lower, between subjects). Means and test statistics are reported in Table 5. In the ANOVA of spoken word recall, significant main effects of spelling condition and reader level and a significant interaction between the two variables were detected. Means in Table 5 reveal that word learning was superior in the spelling-present condition. Higher level readers outperformed lower level readers, and the advantage provided by seeing written words over not seeing written words was much greater among higher readers than among lower readers. The difference in percentages of readers who reached criterion in learning pronunciations with spellings compared to no spellings was much greater among the higher readers (i.e., 79% vs. 29%, for a difference of 50%) than among lower readers (i.e., 28% vs. 0%, for a difference of 28%). Whereas the majority of higher readers reached criterion in learning pronunciations with spellings, only a minority of lower readers reached criterion with spellings. When spellings were not seen, some higher readers (29%) but no lower readers reached criterion in recalling pronunciations. These findings show that giving students written as well as spoken vocabulary words to study exerted a strong impact on their memory for the pronunciations of new vocabulary words, especially students with stronger orthographic knowledge.

In the ANOVA of trials to criterion recalling definitions, significant main effects of spelling condition and reader level were detected, but there was no significant interaction. From mean performance in Table 5, it is apparent that definitions were learned more readily when written words had been seen than when they had not been seen. Also, higher level readers recalled definitions better than lower level readers. These findings show that exposure to spellings helped both higher and lower readers learn the meanings of words. Comparison of performance recalling spoken words and definitions in Table 5 shows that it was easier for students to learn definitions than to remember pronunciations of the words. Most of the higher and lower readers reached criterion in learning

definitions, but many did not reach criterion in recalling pronunciations of the words.

To examine performance over trials, we conducted three-way ANOVAs. The independent variables were spelling condition, reader level, and trials (Trials 1–5). The dependent variables were the number of correct pronunciations recalled in one ANOVA and the number of correct definitions recalled in the second ANOVA. For pronunciation recall, significant main effects of spelling condition and reader level and a significant interaction between these two variables were detected (all *ps* < .01). Performance patterns favored spellings-present over spellings-absent conditions, higher over lower level readers, and a greater advantage of spellings over no spellings among higher readers than among lower readers. Mean performance is displayed in Figure 2. These results duplicate those on the trials-to-criterion measure reported in Table 5.

Of particular interest in this analysis were effects involving trials showing a significant main effect,  $F(4, 27) = 117.19$ ,  $p < .01$ , as well as significant interactions with reader level,  $F(4, 27) = 2.71$ ,  $p = .05$ ; with spelling exposure,  $F(4, 27) = 14.77$ ,  $p < .01$ ; and with Reader  $\times$  Spelling exposure,  $F(4, 27) = 3.81$ ,  $p < .05$ . From Figure 2, it is apparent that spoken word recall improved across trials. Both groups showed better recall of pronunciations with than without spellings after Trial 1. Gains from Trials 1 to 3 were much greater for higher readers learning words with spelling aids than gains in the other three conditions (i.e., higher level readers learning words without spellings, and lower level readers learning words both with and without spellings). After Trial 3, ceiling effects suppressed continued gains of the higher group with spelling aids. In other words, higher level readers derived an increasing advantage over lower level readers from spelling aids in recalling pronunciations as word learning proceeded. These findings reveal a pattern of the rich getting richer as a result of superior orthographic knowledge when spellings were provided during vocabulary learning.

\*  $p < .05$ . \*\*  $p < .01$ .

In the ANOVA of definition recall over trials, significant main effects of spelling condition and reader level were detected. Performance patterns favored spellings present over spellings absent ( $p < .01$ ) and higher over lower level readers ( $p < .05$ ). These results duplicate those on the trials-to-criterion measure reported in

Figure 2. Mean number of pronunciations recalled over five learning trials by higher level readers and by lower level readers in the spelling condition (Sp) and the no-spelling condition (NoSp) in Experiment 2.

Table 5. A significant main effect of trials was detected,  $F(4, 27) = 28.19$ ,  $p < .01$ , but there were no significant interactions between trials and the other variables (all  $ps > .05$ ). As shown in Figure 3, mean performance improved from Trials 1 through 3 in all conditions, but after that performance was close to ceiling. Both

Figure 3. Mean number of definitions recalled over five learning trials by higher level readers and by lower level readers in the spelling condition (Sp) and the no-spelling condition (NoSp) in Experiment 2.

higher and lower readers displayed superior definition recall in the spelling than the no-spelling condition from the very first test trial.

In summary, these findings show that fifth graders benefited from spelling aids in learning new vocabulary words. Effect sizes ranged from moderate to very large (see Table 5). Spoken words and their meanings were learned faster when spellings were seen during study and feedback periods than when they were not. In addition, the higher level readers learned pronunciations and definitions more easily than the lower level readers, and the higher level readers benefited much more from spellings compared to no spellings in recalling spoken words than the lower level readers.

To determine the extent that spelling aids boosted the learning of individual words, we calculated the mean number of correct responses over the first five trials for each student learning each word and averaged these values. Results are presented in Table 3. Comparison of mean recall values revealed that 100% of the spoken words and 80% of the definitions benefited from spelling exposure. These findings show that the advantage of spelling aids for learning both pronunciations and meanings generalized across words as well as students.

Half of the words that students learned contained two syllables, and half were three syllables. Gathercole and Baddeley (1989) found that learning was more difficult when words contained more than two syllables. Table 3 shows the words ordered from easy to difficult on the measure of spoken word recall in the spelling-present condition. Most of the three-syllable words (80%) are found in the bottom 10, harder to learn words. In contrast, most of the two-syllable words (80%) sit among the top 10, easier to learn words. Correlations between the number of syllables and recall values revealed significant negative relationships for recall of pronunciations with spelling aids ( $r = -.59, p < .01$ ) and recall of pronunciations without spelling aids ( $r = -.53, p < .05$ ), but relationships were not significant for recall of definitions ( $r = -.06, p > .05$ , for the spelling condition, and  $r = -.21, p > .05$ , for the no-spelling condition). Clearly, syllable length influenced recall of pronunciations but not of definitions.

Analyses of the errors characterizing students' responses over trials in the word-recall task revealed that learning to pronounce words correctly was the central difficulty. Producing words but matching them to the wrong pictures accounted for only 1% to 2% of the errors. Most errors involved either a failure to respond or a failed attempt at producing the correct pronunciation. In the latter case, mispronunciations bore a closer resemblance to correct pronunciations when spellings had been seen than when they had not been seen. Comparison of the proportion of mispronunciations that shared any syllables or initial sounds with the correct words revealed a significant difference favoring those in the spelling-seen condition ( $M = 30\%$  seen vs.  $17\%$  not seen),  $t(31) = 4.23, p < .01$ . This indicates that spellings strengthened students' memory for partial sounds in the words being learned.

Several posttests were given to assess longer term effects of vocabulary learning, including students' memory for the spoken words depicted in training pictures, their ability to fit the new vocabulary words into cloze sentences, and their memory for the spellings of words. ANOVAs were conducted with spelling condition and reader level as the independent variables. Mean performance and test statistics in Table 5 show that on all of these measures, main effects of reader level and spelling condition were statistically significant. The interaction was significant on the

cloze test and spelling test but not on the spoken-word recall test. As apparent in Table 5, students recalled spoken words, wrote their correct spellings, and embedded words in sentences significantly better when they had learned the words by seeing their spellings than when they had not seen their spellings. These findings show that spelling effects persisted for at least a day beyond the end of training.

Higher level readers outperformed lower level readers on all three posttests, as shown in Table 5. On the spelling and cloze measures, significant interactions resulted from higher level readers benefiting more from spellings than no spellings compared to lower readers. The percentage of words spelled correctly increased from 29% without spellings to 71% with spellings for higher readers but only from 12% without spellings to 33% with spellings for lower readers. The fact that higher level readers had strong memory for the spellings of words they had seen during the word-learning task supports the idea that memory for spellings was the reason that higher readers learned words better when they were exposed to spellings than when they were not.

Posttests also assessed students' memory for the definitions of words and their ability to recognize which of four previously unseen pictures depicted each vocabulary word. Performance of both higher and lower readers was virtually perfect in both of these tasks, with means of 99% to 100%. Thus, students had no difficulty remembering or recognizing the meanings of the new vocabulary words 1 day later regardless of whether spellings had been seen.

Correlations between the literacy and language measures (i.e., Boder word reading, Ganske word spelling, TOWRE nonword reading, PPVT vocabulary recognition) and performance on the vocabulary learning tasks were examined. In the learning tasks, the measure of spoken word recall was the mean performance on Trials 1 through 5. The measure of definition recall was the number of trials to criterion, because ceiling effects suppressed individual differences on the measure with one to five trials. The literacy measures (i.e., word and nonword reading and spelling) were highly related to each other (correlations ranging from .69 to .82), indicating that there was much overlap in the skills assessed. Reported below are the statistically significant correlations at  $p < .05$ . Note that negative correlations associated with recalling definitions resulted from the trials-to-criterion measure, with lower scores reflecting faster learning.

For learning with spelling aids,

1. recalling pronunciations: .71 (reading words), .66 (spelling words), and .56 (reading nonwords);
2. recalling definitions:  $-.41$  (reading words) and  $-.41$  (spelling words).

For learning without spelling aids,

1. recalling pronunciations: .59 (spelling words) and .45 (reading nonwords);
2. recalling definitions:  $-.41$  (reading words),  $-.67$  (spelling words), and  $-.51$  (reading nonwords).

These results reveal the heavy influence of word reading and spelling skills in all of the vocabulary learning tasks. At least two

possible explanations can be identified for the strong relationship between spelling ability and recall of pronunciations and meanings when spellings were not seen. The better spellers might have been more strategic and spontaneously imagined spellings to help them store the words in memory. Alternatively, better spellers may have richer, more elaborated phonological memories as a result of acquiring more extensive knowledge of mapping relations between graphemes and phonemes. In contrast to Experiment 1, which revealed a significant correlation for second graders, scores on the PPVT-III vocabulary test were not significantly correlated with the definition learning measures for fifth graders (i.e.,  $r_s = -.03$  and  $-.15$ ,  $p_s > .05$ ). Rather, word reading and spelling abilities were more related to definition scores than was receptive vocabulary knowledge. Why this occurred is not clear. PPVT-III scores were not correlated with word reading or spelling scores either (i.e., correlations ranged from  $-.02$  to  $.16$ ,  $p_s > .05$ ).

### GENERAL DISCUSSION

In summary, the results of both experiments yield several important findings. Elementary school students learned and remembered the pronunciations and meanings of new vocabulary words better when they were exposed to written forms of the words during study periods than when they only heard and repeated the words. The advantage was evident on delayed posttests assessing transfer as well as training effects. Spelling aids proved advantageous for learning most, if not all, of the individual vocabulary words' pronunciations and meanings, suggesting that the effect applies to the learning of words in general. The advantage of spelling aids was evident among fifth graders as well as second graders, indicating that the benefit was not limited developmentally. Higher level fifth-grade readers, who had superior orthographic knowledge, benefited more from spellings than lower level fifth-grade readers. In fact, higher level readers made increasingly greater gains from one trial to the next with spelling aids compared to gains with no spelling aids and compared to the gains made by lower level readers. Learning and remembering the pronunciations of new vocabulary words proved harder than learning definitions of the words, so exposure to spellings helped students with the more difficult part of vocabulary learning.

The advantage provided by spelling exposure in learning pronunciations and meanings of new vocabulary words can be explained by Ehri's (1992) theory of word learning. According to the theory, word learning entails the amalgamation of various word identities in memory, including orthographic, phonological, and semantic identities. When readers hear an unfamiliar word and comprehend its meaning, an amalgamated representation combining phonological and semantic identities begins to form in memory. If readers also view the word's written form, connections are activated between graphemes in the spelling and phonemes in the pronunciation. These connections bond the spelling to its pronunciation, and the word's orthographic identity is added to its representation in memory. Because pronunciations of words are fleeting, graphemes in spellings serve to clarify phonemic constituents in memory. Written words also represent pronunciations in another modality as a visual image that enhances the word's memorability, according to dual coding theory (Sadoski & Paivio, 2001). Thus, when spellings of new words are seen and pronunciations are heard, students are able to form stronger, better specified phono-

logical representations in memory earlier during the learning process than when spellings are not seen. Earlier formation of pronunciations in memory speeds up the incorporation of semantic identities into the representations as well.

In the present study, several findings were consistent with this theory. When students misrecalled pronunciations of words, they preserved more correct sounds in the spelling exposure condition than in the no-exposure condition. This supports the idea that spellings became connected to pronunciations and enhanced memory for their parts during learning. Students began to recall pronunciations and meanings of words earlier during the learning trials when they saw spellings than when they did not. This supports the idea that spelling-based amalgams began to form in memory sooner than amalgams without spellings. Posttest performance occurring 1 day after learning revealed that students wrote vocabulary words more accurately when they had seen them than when they had not, indicating that spellings of specific words were stored in memory.

Several alternative explanations for facilitation can be dismissed. It was not the case that students in the spelling aids condition were exposed to words more frequently. A tally revealed that, in fact, exposure was greater in the spelling-absent condition. It is not likely that seeing spellings caused children to repeat words more accurately, thus improving the quality of their phonological representations in memory. The words contained familiar sounds, syllables, and blends. Children had no trouble repeating them correctly and easily in the spelling-absent condition, and, in fact, they repeated them more frequently than in the spelling-present condition.

It is not likely that seeing spellings induced students to apply a decoding strategy to sound out and blend the words, thus giving them extra practice. Our procedures limited the need for this because the experimenter spoke the words as soon as they were shown. Also, the written words were visible for a matter of seconds, thus limiting rehearsal time. Procedures were, in fact, structured to give more practice to students in the no-spelling condition. They heard and pronounced the words more times than students in the spelling condition. No child who viewed written words was observed to overtly decode them. It is more likely and consistent with our preferred explanation that these children engaged in a different form of decoding. When they saw spellings and heard or spoke pronunciations, they automatically computed the connections between graphemes and phonemes to determine how spellings mapped onto pronunciations. It is this orthographic mapping process that, in our view, explains what students did when they saw and heard written words and accounts for the effect of seeing spelling on vocabulary learning.

Another reaction to our findings might be to dismiss them as patently obvious because two modalities should always be better than one. However, in the case of vocabulary learning, it is not clear that combining visual and verbal modalities in the form of spellings and pronunciations should make vocabulary learning any better. First, the phonological working memory theory of Gathercole and Baddeley (1993) does not regard spellings of words as strengthening memory for their phonological representations. Neither have vocabulary researchers been explicit about how spellings contribute to vocabulary learning. In addition, older theories of the reading process have assigned a peripheral role to spellings in lexical memory. According to Goodman (1976), letter cues in

words are merely sampled during text reading rather than accessed in memory. According to Gough (1972), readers transform written words into blends of phonemes by applying grapheme-phoneme knowledge and then use the phonological forms of words to retrieve their meanings in memory. With practice, the transformation process speeds up, but the written forms of words are not mapped onto pronunciations in memory. According to some versions of dual route theory, written words are stored in memory, but as nonphonological forms linked to meanings (i.e., the direct, visual route; e.g., Barron, 1986). Thus, it is not obvious that two modalities should be better than one in the case of storing new vocabulary words in memory.

Observations of children's comments during the word learning trials bolster the claim that spellings themselves were stored and accessed to enhance memory for pronunciations. In the spelling-present condition of Experiment 1 during the word recall trials, 2 students remembered and orally named letters in the spellings of words before pronouncing them. A 3rd student was observed to cover her eyes while trying to pronounce the word, effectively trying to "see" the image of the word's spelling. Likewise, in Experiment 2, in the spelling aid condition during test trials when spellings were not present, 2 students orally recalled the names of letters in the words before attempting to pronounce them. Another student mispronounced the word on the test trial and then, on being shown the training card, said, "Oh, I misspelled it." A 4th student, when trying to recall the word *hicatee*, said, "I know there are two *es* at the end." These observations suggest that students had formed orthographic representations and attempted to use them to "read" pronunciations of words from memory.

Results of the present study replicate those of Ehri and Wilce (1979), who found that second graders learned the pronunciations of nonwords better with spelling aids than without them. Our findings extend their work by showing that spelling aids facilitated the learning of real words, including their meanings as well as pronunciations. Also, our findings show that spelling aids benefited vocabulary learning in older students. There was uncertainty about this. One reason why older students might not show much effect is that, compared to beginning readers, they possess more extensive decoding proficiency and phonological and orthographic knowledge of words. Conversely, when faced with the task of learning vocabulary words that are multisyllabic and, hence, harder to remember than CVC words, older readers might show an even larger effect than younger readers.

Findings support the latter hypothesis. Although different words were learned by the older and younger students, the words were not more difficult relative to the students' age and grade level. About the same percentage of students reached criterion in learning their set of words (i.e., 50% of second graders and 50% of fifth graders learned words with spellings, and 15% of second graders and 13% of fifth graders learned words without spellings). This comparability allows us to compare the effect sizes for older and younger students. On the measure of trials to criterion learning pronunciations of the words, the effect sizes favoring spelling aids over no spellings were  $-1.67$  (fifth-grade higher level readers),  $-0.86$  (fifth-grade lower level readers), and  $-0.61$  (second-grade readers). Thus, fifth graders showed bigger effects of spelling aids than second graders, especially fifth graders who were the higher level readers. These findings suggest two factors that magnify the benefit of spelling aids in learning new words: the number of

phonemes and syllables, and learners' knowledge of the orthographic system.

Other studies have reported word length effects on children's pronunciations of words. Gathercole and Baddeley (1989) found that nonwords longer than two syllables were harder for 4- and 5-year-olds to repeat than shorter words, and difficulty increased with word length. The present findings are consistent. Fifth graders had a harder time recalling the pronunciations of three-syllable words than two-syllable words during the learning trials, despite facilitation effects provided by spelling aids.

The essence of vocabulary learning is linking pronunciations to meanings of new words in memory. Gathercole and Baddeley (1993) provided theory and evidence explaining how phonological representations of new words are established in memory. A key process is phonological short-term memory, which maintains the word in working memory until a more permanent phonological representation is stored. Good readers are known to have better phonological working memories for words than poor readers, and this is thought to explain differences in vocabulary learning. The present findings, however, suggest that phonological memory may be less important than orthographic knowledge for explaining good-poor reader differences in learning the pronunciations of new vocabulary words when spellings of the words are seen. Comparison of the performance of higher and lower level readers in Figure 2 shows that the higher readers outperformed the lower readers only modestly and only on later trials in learning pronunciations from their spoken forms alone. However, higher readers were far superior to lower readers in learning pronunciations when they had the opportunity to amalgamate spellings to phonological representations of words in memory. This suggests that when students acquire strong orthographic skills and when new vocabulary words are read rather than just heard, orthographic processes lessen their dependence on phonological working memory for storing new vocabulary words in memory.

It is interesting that in the present study, we found that students' orthographic knowledge was strongly correlated with their memory for spoken words when spellings were not seen as well as when they were seen. This suggests that becoming literate in an alphabetic writing system facilitates phonological memory in general, not just when written words are seen. In a longitudinal study, Gathercole and Baddeley (1989) found that short-term working memory effects on vocabulary learning were diminished in children above 6 years of age. Whereas the correlation between vocabulary and nonword repetition scores ranged from .52 to .56 among children between the ages of 4 and 6 years, it declined to .28 at 8 years of age. The authors attributed the decline to older children's accumulation of more spoken words in memory and more practice repeating words (Gathercole, 2006). However, our findings suggest another explanation: that diminution results from the emergence of literacy skills, in particular the acquisition of orthographic knowledge and the linkage of spellings to the phonological forms of words in memory. This possibility invites further research.

The impact of orthography on phonological processing in tasks other than vocabulary learning has been documented (Ehri, 1984, 1985, 1993). Spellings of words have been found to influence how people segment words into phonemes and syllables, what sounds they conceptualize in words, and how quickly they distinguish spoken pairs of rhyming words that either share or do not share

spellings (e.g., *foam–roam* vs. *bomb–comb* vs. *goal–bowl*). However, such effects appear not to be generally recognized. Gathercole's (2006) work "Nonword Repetition and Word Learning: The Nature of the Relationship" appeared as a keynote article in a special issue of *Applied Psycholinguistics*. It was followed by 14 commentaries, none of which raised the possibility that orthographic representations of words might be important.

The present findings show the importance of students' acquisition of strong orthographic knowledge to benefit vocabulary learning. Fifth graders with better orthographic knowledge outperformed those with weaker knowledge on the training measures as well as on the posttests. Most impressive were the increasingly large gains over trials that higher level readers made when the pronunciations of words were learned with spellings compared to the gains made with no spellings and compared to the gains made by lower level readers (see Figure 2). The fact that higher level readers showed a much steeper slope in learning the pronunciations of words with spelling aids than lower level readers suggests a Matthew effect (Stanovich, 1986), with the rich getting richer in expressive vocabulary during the course of learning as a result of superior orthographic knowledge. Whereas a Matthew effect was observed in learning pronunciations, it was not observed in learning definitions, for which a ceiling effect might have suppressed differences.

Given these findings, it is perhaps surprising that higher readers did not show larger vocabularies than lower readers on the PPVT receptive vocabulary test. It may be that a Matthew effect was limited to expressive use of new vocabulary words that had been learned with spelling aids, or it may be that the PPVT-III test lacked sufficient sensitivity with this population of low-socioeconomic status, minority students who had below average vocabularies. Which is true awaits further study.

The fact that written words were processed and remembered at all during the learning trials might surprise some researchers, given that no attention was drawn to them and that the words did not have to be read because the experimenter pronounced them when they were shown. Also, pictures of the words were shown, and there is some research indicating that written words are overlooked when pictures accompany them (Sadoski, 2005). Our findings can be interpreted to bear on Share's (1995, 1999, 2004) self-teaching mechanism by raising a question about how it might operate. Share claimed that learners apply a decoding procedure to retain information about the spellings of words in memory. However, the present findings suggest that it is not the conscious application of a decoding strategy (i.e., sounding out letters and blending them) that is critical for memory but rather the implicit, spontaneous activation of mapping relations that connect graphemes to phonemes when spellings are seen and pronunciations are heard. A question for future research is whether students in the present study would have benefited even more from spelling aids if their attention had been directed to the spellings and if they had been instructed to decode the words aloud before the experimenter pronounced them.

Although the advantage was less than that for higher level readers, it is noteworthy that fifth-grade, lower level readers still benefited from spelling aids in their vocabulary learning. This benefit occurred despite the fact that their decoding proficiency on the TOWRE test was well below grade level (i.e., mean grade equivalent = 2.2). A smaller effect might have resulted because

graphophonemic mapping relations were formed but were partial and not as well secured to pronunciations of words in memory.

In the present study, very few learning trials were needed for spelling aids to facilitate word memory (see Figures 1–3). A clear advantage favoring spellings for learning pronunciations was evident by Trial 2 for second and fifth graders. A clear advantage for definitions was evident by Trial 1 for fifth graders and by Trial 2 for second graders. Share (2004) also observed that as few as one learning trial was needed for third graders to retain orthographic information about words in memory. How might such rapid learning be explained? Stuart and Coltheart (1988) identified one possible contributing factor. They suggested that orthographic knowledge provides learners with a basis for expecting specific connections between spoken and written words. For example, students who know how to segment the word *man* into three phonemes and how to spell each phoneme will expect to see the word written *m-a-n* before they ever see it. According to this hypothesis, spelling expectations may support very rapid acquisition because word learning simply entails confirming what is already known.

One striking finding in the present study was that during the learning trials, it was much easier for students to hear words and recall their meanings than to see pictures of the words and recall their pronunciations. Meanings might have been easier to learn because there were only a limited number, 6 in Experiment 1 and 10 in Experiment 2. In contrast, pronouncing words accurately required remembering novel blends of many phonemes, 18 in Experiment 1 and 61 to 63 in Experiment 2, with some phonemes repeated in different words. The difficulty of recalling and pronouncing the correct blends was evident in students' errors. They sometimes mixed up parts from different words—for example, *tamookie* (*tamarack* plus *koomkie*), *friboscis* (*proboscis* plus *fribble*), and *kerfello* (*kerfuffle* plus *scrivello*). In Experiment 2, involving 32 students, this happened 45 times during Trial 1, 61 to 65 times during Trials 2 to 4, and 42 times during Trial 5.

Dual coding provides a theoretical explanation for the ease of learning word meanings in the present study. In their theory, Sadoski and Paivio (2001) distinguished a verbal memory system and a nonverbal imagery system. In the present study, procedures for teaching word meanings utilized both visual and verbal systems. The words were concrete nouns, their meanings were easily constructed from students' experiences, and they were taught with pictures that facilitated the formation of images in memory. Also, the nouns were embedded in verbal definitions and sentence contexts to clarify their position in students' web of linguistic and world knowledge. Sadoski (2005) and Sadoski and Paivio reviewed studies showing that these factors are especially effective for enhancing memory. Dual coding theory's constructs might be incorporated into Ehri's (1992) amalgamation theory to better explain how semantic identities of words are learned.

### Strengths and Limitations

In the present study, the contribution of spelling aids to vocabulary learning was examined via a controlled laboratory task to exclude the confounding or obscuring effects of other variables. Findings clearly reveal that spelling aids provided a major boost. Although these effects were found with direct, individualized instruction, there is no reason to believe that the same boost from

spellings would not also result when vocabulary words are taught to classrooms of students or when students encounter new words in print on their own, provided that the pronunciations and meanings of the written words are apparent to readers. These possibilities should be investigated.

One strength of the present study is that expressive vocabulary acquisition was studied. It is much harder to teach children to produce new words than to teach them to recognize words' meanings (Senechal, 1997). Present findings indicated that showing students spellings of words strengthens their ability to pronounce and use the words in speech.

Another strength of the present study is that a counterbalanced design with random assignment was used to detect the benefits of spelling aids. Students received vocabulary instruction both with and without spelling aids. Almost every student was found to learn words and definitions better when spellings were present than when they were not, regardless of the particular words they learned in each condition and the order in which the two tasks were completed. Therefore, even though the samples were relatively small, the effects were robust.

Some limitations of the study can be identified. The words taught were concrete nouns, which are easier to learn than other parts of speech (Elley, 1989). The words represented concepts already familiar to children rather than unfamiliar concepts. Also, the words' spellings conformed to the English writing system, making them easier to remember than less regularly spelled words (Ehri, 1997). Children's memory for the words was tested after a delay of 1 day, whereas the goal of vocabulary instruction is long term. The participants were second and fifth graders whose parents provided written consent. Further research is needed to show that findings generalize to other types of words, participants, and testing conditions.

Students were sampled from urban, low-socioeconomic status schools with large minority populations, and their vocabulary levels were well below national norms on the PPVT-III test. Nevertheless, it is likely that findings generalize to other populations of students. The Ehri and Wilce (1979) study was conducted with middle class, primarily Caucasian students, and results showed the same benefit of orthography for recall of pronunciations. Biemiller and Slonim (2001) compared children with smaller vocabularies to those with larger vocabularies in Grades 3 through 6 and found that gains in vocabulary growth were comparable in the two groups.

### Implications for Instruction

The present findings carry several important implications for the teaching of vocabulary in schools. One implication involves teachers' and students' awareness of the contribution of orthography. If teachers are not aware of its importance, they may overlook it in their teaching. For example, when they encounter words that their students are unlikely to know as they are teaching a lesson, they may explain the meanings of the words orally without writing them on the board. When they review harder words before or after they have read a text orally to their class, they may define the words orally but not write them. Teachers who make a point of showing the written forms of words as part of vocabulary instruction do so on the basis of common sense rather than on the basis of empirical evidence, which has been meager prior to this study,

or the recommendations of vocabulary instruction experts, who have largely overlooked the contribution of spellings, as reported earlier in this article.

Also, students may overlook the written forms of unfamiliar words as they read text. They may not make the effort to sound out spellings but rather may skip over them and substitute synonyms. In fact, skipping and guessing are commonly taught strategies. The present study provides clear evidence that these are not the best strategies for vocabulary learning and that students need to see, hear, and say unfamiliar words whose meanings are being learned because this strengthens their memory for spellings, pronunciations, and meanings of the new words.

On the basis of the present findings, several procedures can be recommended that hold the promise of making teachers' vocabulary instruction more effective. When teachers explain the meanings of words, they should also show students their written forms, tell students how to pronounce the words, and help students analyze how spellings map pronunciations, including grapheme-phoneme correspondences as well as larger syllabic and morphographic units. These steps should help students retain spellings, pronunciations, and meanings of new vocabulary words in memory.

Hatch and Brown (1995) recommended helping learners retain clear images of written words in memory to combat confusions among similar sounding words, especially for English language learners. As evidence, they cited numerous examples of mistakes made by students of English as a second language in defining English words—for example, a Spanish speaker who defined *happened* as *felices*, meaning *happy*. If students had seen the spelling and had possessed sufficient knowledge of the orthographic system, they might not have considered this meaning. The value of spellings for learning a second language may be especially high because graphemes help to clarify the particular phonemes and morphemes in words, thereby securing a more precise representation in memory. Many second-language learners report heavy reliance on orthography for building their vocabularies (Hatch & Brown, 1995).

Researchers studying foreign language acquisition have recognized the contribution of orthography to vocabulary learning. Sparks et al. (1997) examined high school students learning a foreign language. They found that word decoding skill was the best predictor of year-end foreign language oral proficiency, better even than students' grades in their foreign language class the previous year. The authors interpreted their findings to show the utility of print for building representations of spoken language in memory.

Another possible implication of the present findings involves the importance of systematic phonics instruction. This approach to teaching beginning reading may provide the foundation for more effective vocabulary learning by developing students' knowledge of the orthographic system. This, in turn, should improve their ability to learn and remember new vocabulary words, as shown in the present study. This speculation invites more research.

A third instructional implication involves the value of teaching a learning strategy to enhance students' expressive vocabulary. Older students are thought to learn the bulk of new words through reading (Chall et. al., 1990), and much of this is conducted silently. The findings of Shu, Anderson, and Zhang (1995) confirm that students learn new word meanings when they read text silently.

However, it is not clear whether they learn the pronunciations of new words as well, for this was not studied. A question of interest given the present findings is whether pronunciations are learned along with meanings when text is read silently and whether instructors could enhance this learning by teaching students to stop and say aloud any unknown words they encounter. According to the present findings, this strategy should enhance grapheme-phoneme processing and, hence, the retention of pronunciations along with meanings in memory. This possibility invites further research.

To conclude, we quote from an anonymous reviewer's evaluation of our study:

The research conducted in this study makes a significant contribution to reading theory and practice in that it ties together the orthographic/phonological system with the meaning system in ways not previously thought. The researchers show quite clearly that students who see the spellings of words actually learn the meanings of the words more easily. This is quite a remarkable finding. I know of no research on vocabulary learning or vocabulary instruction that rests on such a claim. The emphasis in the vocabulary literature is on learning the meanings of words, not on the value of seeing the words and tying together knowledge from the different systems. Because of this connection, the research makes a significant contribution to reading theory and also has specific and practical application to everyday practice in a way that few research studies do.

# Early Identification of Reading Difficulties Using Heterogeneous Developmental Trajectories

Christy Kim Boscardin and Bengt Muthén  
University of California, Los Angeles

David J. Francis

Eva L. Baker  
University of California, Los Angeles

Serious conceptual and procedural problems associated with current diagnostic methods call for alternative approaches to assessing and diagnosing students with reading problems. This study presents a new analytic model to improve the classification and prediction of children's reading development. Growth mixture modeling was used to identify the presence of 10 different heterogeneous developmental patterns. In all, 411 children in kindergarten through Grade 2 from 3 elementary schools in Texas were administered measures of phonological awareness, word recognition, and rapid naming skills 4 times a year. The mean ages were 5.8 years ( $SD = 0.35$ ) for the kindergartners, 6.9 years ( $SD = 0.39$ ) for Grade 1, and 8.0 years ( $SD = 0.43$ ) for Grade 2; the percentage of boys was 50%. The results indicate that precursor reading skills such as phonological awareness and rapid naming are highly predictive of word reading (word recognition) and that developmental profiles formed in kindergarten are directly associated with development in Grades 1 and 2. Students identified as having reading-related difficulties in kindergarten exhibited slower development of word recognition skills in subsequent years of the study.

*Keywords:* reading development, screening, reading skills, achievement, longitudinal studies

Recently, with mounting evidence for early detection as the key to remediation and prevention for later reading difficulties, there has been a growing interest and urgent call for earlier identification of children with reading difficulties. According to research funded by the National Institute of Child Health and Human Development (National Reading Panel, 2000), if intervention is delayed until 9 years of age (the time when most children with reading difficulties typically receive services), approximately 75% of children will continue to have reading difficulties in later grades (Lyon, 1998). The majority of children identified as having reading difficulties in early grades will continue to have problems in later grades without appropriate instructional intervention (Juel, 1988; Scarborough, 1998). Satz and Fletcher (1988) suggested that interventions are most effective if implemented prior to the overt manifestation of disability. Schenck, Fitzimmons, Bullard, Taylor, and Satz (1980) also concluded that children at high risk who received intervention

early demonstrated significant improvement in academic performance over time. Earlier studies have shown that older children who were identified as having reading difficulties would not have required learning disability status if their difficulties had been diagnosed and they had received intervention at an early age (De Hirsh, Jansky, & Langford, 1966; Strag, 1972).

Previous studies have shown that overall academic success in later grades can be predicted with reasonable accuracy by using reading outcomes at early grades (Slavin, 1994; Strag, 1972; Torgesen & Wagner, 2002). Previous longitudinal studies have also suggested that children at risk for reading difficulties can be identified much earlier than previously thought (Juel, 1988; Shaywitz, Escobar, Shaywitz, Fletcher, & Makuch, 1992).

## Identification With IQ Discrepancy-Based Method

Despite the importance of early detection, previous methods for identifying children with reading difficulties suffered from the lack of a theoretical foundation and supportive evidence for validity, which unnecessarily delayed identification (Lyon et al., 2001). Previously, children were identified as having reading difficulties if there was a substantial discrepancy between a child's aptitude, typically operationalized by IQ, and his or her reading performance (Francis, Fletcher, Shaywitz, Shaywitz, & Rourke, 1996; Gunning, 1998). Although the IQ discrepancy-based method has been the most widely used definition of reading difficulty, there were several conceptual and measurement problems that warranted an alternative method of identification of persons with dyslexia and other poor readers (Francis, Shaywitz, Stuebing, Shaywitz, &

Fletcher, 1996; Shaywitz et al., 1992). Dissatisfaction with previous approaches to identification of children with reading difficulties led to consideration of alternative approaches such as Response to Intervention (RTI) in the recent reauthorization of the Individuals with Disabilities Education Act. The core concept of RTI is based on the premise that a student exhibiting a slower rate of development and failure to respond adequately to intervention may be identified as requiring special services and being at risk for learning disability (Fletcher, Coulter, Reschly, & Vaughn, 2004). With RTI, the focus is on screening, instructional intervention, and continual monitoring. Proponents of the RTI approach suggest that with continuous progress monitoring, the focus will be shifted to prevention and intervention rather than relying on the current "wait-to-fail" model facilitated by the use of IQ-discrepancy approaches (Compton, Fuchs, Fuchs, & Bryant, 2006). Early and accurate identification of students at risk for reading difficulties will be fundamental to successful implementation of the various RTI models proposed (Bradley, Danielson, & Hallahan, 2002; Compton et al., 2006; Fuchs, Mock, Morgan, & Young, 2003). As illustrated by use of the IQ discrepancy-based method in the past, using test scores from a single time point is often unreliable and insufficient for identification of reading difficulties.

Early identification of children with reading difficulties will require a system that accurately predicts which children are at risk for reading failure. However, previous screening procedures have yielded unreliable results due to high rates of classification and measurement errors (Fletcher & Satz, 1984; Jenkins & O'Connor, 2002; Scarborough, 1998). Speece (2005) suggested that one of the reasons for the rate of inaccuracy and the problems associated with early identification is lack of consideration and disregard for potential change and growth in the reading development process. Considering that growth and development are fundamental to the concept of learning, it seems only logical to consider growth (longitudinal) data as the primary source for the identification of reading problems.

### Predictors of Reading

Much progress has been made in the past 20 years in understanding the correlates of reading development and the key predictors of reading outcomes (National Reading Panel, 2000; National Research Council, 1998). One of the most significant predictors of early difficulties in acquiring accurate and fluent word recognition skills has been identified as the individual differences in phonological skill (Jenkins & O'Connor, 2002; Liberman, Shankweiler, & Liberman, 1989; Parrila, Kirby, & McQuarrie, 2004). There seems to be a wide consensus that deficits in phonological awareness are related to later reading difficulties (Catts & Kamhi, 1999; Stanovich & Siegel, 1994; Torgesen, Wagner, Rashotte, Burgess, & Hecht, 1997). More recently, some studies have suggested that deficits in both phonological awareness and in serial naming speed may produce more severe reading difficulties, providing evidence in favor of the double-deficit model (Morris et al., 1998; Schatschneider, Carlson, Francis, Foorman, & Fletcher, 2002; Wolf & Bowers, 2000). However, investigation of the relationship between these two skills on reading development over time and the relative importance of these two skills in early identification of children with reading difficulties

has been limited. In this study, we examined the relationship between the development of precursor skills such as phonological awareness and rapid naming and the development of word recognition skill in later grades.

In light of the current call for alternative approaches to identification of students with reading difficulties, we offer a novel approach to examining reading development through the application of a new longitudinal clustering technique called *growth mixture modeling*. The purpose of this study was to determine whether distinctive groups of students with various developmental profiles can be identified based on precursor reading skills and whether these profiles will help characterize the course of reading difficulties manifested during different developmental periods. Analysis of individual growth curves based on early reading skills is an alternative statistical approach that will potentially be helpful in earlier identification of students with reading difficulties. These individual growth curves may not only yield earlier diagnosis of reading difficulties but may also provide contextual data for further analysis of individual differences and problems.

### *Growth Modeling*

Conventional growth modeling has been a useful technique for examining individual differences in learning development (Bryk & Raudenbush, 1992; Jennrich & Schluchter, 1986; Laird & Ware, 1982; Lindstrom & Bates, 1988; Muthén, Khoo, Francis, & Boscardin, 2002). To study development or change over time, the researcher represents individual outcomes using rates of growth over multiple time points. In growth curve models, individual reading development can be formulated in terms of initial reading level and the rate of learning or development of reading. Typically, the analysis of individual change is represented using random coefficient modeling. Individual change and growth over time can be represented through growth models in order to provide a more dynamic view of reading development.

### *Growth Mixture Modeling*

More recently, a new modeling technique that takes into consideration the effects of heterogeneity in a sample to provide more reliable predictions for later development has been introduced (Muthén, 2000; Muthén et al., 2002; Muthén & Muthén, 2000). Because the conventional growth modeling approach estimates the variation in growth curves as a function of growth factors, interactions of growth factors are difficult to detect and model. In contrast, in the growth mixture modeling framework, interactions between heterogeneous individual growth curves and background factors can be examined without the restrictions of conventional growth modeling techniques. Because growth mixture models allow for the effect of covariates to differ based on the developmental profiles, researchers can determine the relationship between rapid naming skills or a student's background on his or her developmental trajectory. Consequently, the application of growth mixture modeling is extremely useful for developing intervention protocols, as well as identifying specific problems related to development of particular reading skills and to other factors that may contribute to individual differences in development. Growth mixture modeling offers significant advantages over conventional

growth modeling techniques (Muthén, 2000; Muthén et al., 2002). Muthén et al. provided precursory examination of how growth mixture modeling can be used for the identification of several different developmental profiles. In the current study, we expanded on the previous studies on the utility of growth mixture modeling to determine whether distinctive groups of students with various developmental profiles can be identified. Specifically, given the importance of phonological awareness skills in early readers, we examined (a) the relationship between initial status and development of phonological awareness during early stages of reading development and of word recognition skills as well as (b) the contribution of rapid naming skills in differentiating poor readers.

Method

Sample

The sample for the current study was drawn from a larger study consisting of 945 students from a cohort-sequential longitudinal study designed to assess the development of early reading skills (Schatschneider et al., 2002; Schatschneider, Fletcher, Francis, Carlson, & Foorman, 2004; Schatschneider, Francis, Foorman, & Fletcher, 1999). The cohort-sequential longitudinal design for sample selection is presented in Table 1. The larger study sample represented a random selection of children in kindergarten through Grade 2 from three elementary schools in Texas. The students represented a random selection (80%) of students who had parental consent to participate in the study. Students with evidence of severe emotional problems, uncorrected vision problems, hearing loss, acquired neurological disorders, or classification at the lowest level of English as a second language based on school designation were excluded from the study. Children referred for special services in kindergarten were also excluded from participating in this study. Students with later referrals for special education services, however, were included in the study. Measurements of early reading skills were taken four times a year from kindergarten through Grade 2. During a given academic year, students were tested four times (October, December, February, and April) on measures related to reading skills.

For our research purposes, the 411 students with complete data for at least kindergarten and Grade 1 were selected out of the original 945 students for the present study. There were no statistically significant differences between the original sample and this subset on any of the measures. Out of these 411 students, only 208 students had complete data for all three grades. Loss of Grade 1 and Grade 2 in this subset was due to the termination of the study, which prevented us from following some students into Grade 2, and one school's decision not to participate in Year 4. For the

subset of children who had at least complete data in kindergarten and Grade 1 ( $n = 411$ ), about 50% of the sample were boys. The ethnic breakdown of the subset sample was 55% White, 17% African American, 16% Hispanic, 11% Asian, and 1% other ethnicity. The mean ages were 5.8 years ( $SD = 0.35$ ) for the kindergartners, 6.9 years ( $SD = 0.39$ ) for Grade 1, and 8.0 years ( $SD = 0.43$ ) for Grade 2. For the purposes of the present study, White and Asian students were considered to be nonminority, whereas Black, Hispanic, and other students were categorized as minority. The Hollingshead (1975) Four Factor Index of Social Status survey administered to parents was used to collect data on socioeconomic status (SES): (a) 8% were classified as lower class, (b) 40% as working class, (c) 45% as middle-upper class, and (d) the remaining 7% did not provide these data.

Measures

A skills assessment battery was administered individually to each child in October, December, February, and April between kindergarten and Grade 2. Kindergarten students were assessed in phonological awareness and rapid naming. In first and second grades, students were assessed in word recognition. Descriptive statistics on the measures are shown in Table 2.

Phonological Awareness

The phonological awareness test that was administered was an experimental version of the Comprehensive Test of Phonological Processes developed by Wagner, Torgesen, and Rashotte (1999). A detailed description of the test is provided in Schatschneider, Fletcher, Francis, Carlson, and Foorman (2004). The assessment consisted of seven subtests, including (a) phoneme segmentation, (b) phoneme elision, (c) sound categorization, (d) first sound comparison, (e) blending onset and rime, (f) blending phonemes into words, and (g) blending phonemes into nonwords.

*Phoneme segmentation.* This task required children to listen to words and then tell the interviewer “each sound you hear in the word in the order that you hear it.” There were 4 practice items and 15 test items, consisting of one- and two-syllable words with two to five phonemes (e.g., *ate*, *up*, *jump*).

*Phoneme elision.* For the test for phoneme elision, the child was asked to say the word after deleting a specific phoneme (e.g., “Say the word *cup*. Now tell me what word would be left if I said *cup* without the /k/ sound”). There were 4 practice items and 15 test items. All phonemes deleted were consonants. The first 12 items were three-phoneme single-syllable words, for which the deletion was at the end of the word for the first 6 items and the beginning of the word for the other 6 items. The last three items were three- to five-phoneme two-syllable words for which the consonant to be deleted was in the middle (e.g., *ti[g]er*).

*Sound categorization.* This task asked a child to select one of four words that did not share a phoneme with the rest (e.g., “In the set of *fun*, *pin*, *bun*, and *gun*, select the one that doesn't sound like the others”).

*First sound comparison.* In this task, the child was asked to point to the picture of the word that begins with the same sound as the presented word. For example, a booklet with pictures of a rug, a saw, and ash was presented, with a target word of *rake*. The

*Note.* Test scores are item response theory (IRT) scores, standardized to have a mean of 0 and a standard deviation of 1.

correct response in this example is *rug*, which corresponds to the first sound of *rake* (Schatschneider et al., 2004).

**Blending onset and rime.** This task required the child to pronounce a word after the onsets (initial consonants or consonant cluster in a syllable) and rimes (vowels and remaining consonants of the word) had been combined. There were 15 test items, with the number of phonemes in the single-syllable words varying from three to four (e.g., *mouse*, *child*).

**Blending phonemes into words.** This task was identical to blending onset and rime except that in this task the child was asked to blend phonemes rather than onsets and rimes. The child was presented with a string of phonemes at a rate of two per second and asked to repeat them by putting the sounds together. There were 6 practice items and 15 test items (one- and two-syllable words) consisting of two to six phonemes (e.g., *i-f*, *t-oy*, *w-a-sh*, *b-a-m-b-oo*).

**Blending phonemes into nonwords.** This task was identical to blending phonemes into words except that nonwords were used in place of real words, with a parenthetical real word rhyme or near rhyme provided as a pronunciation key (e.g., *i-th [with]*, *y-a-s [gas]*, *th-u-ng [rung]*).

Internal consistency estimates for the subtests ranged from .85 to .95 on all occasions. With respect to concurrent validity, the subtests were correlated with the Lindamood Auditory Conceptualization Test (Lindamood & Lindamood, 1979). Correlations ranged from .41 to .75. For the analysis, we combined the scores on these seven phonological awareness tasks into one latent ability score. Instead of using raw total scores of phonological ability, we used item response theory (IRT) scores based on estimates of each person's latent phonological trait to represent phonological awareness with a mean of 0 and a standard deviation of 1.

### Word Recognition

Skills in word recognition were assessed in Grades 1 and 2 by asking students to read aloud 50 words on 4 × 6-in cards. The Grade 1 and Grade 2 lists each consisted of 50 words, with 16 words in common across the two grades. The 50 words included 36

single-syllable, 11 two-syllable, and 3 three-syllable real words. Words were matched for frequency of occurrence (Carroll, Davies, & Richman, 1971) and spanned first- through third-grade levels of difficulty. The internal consistency estimates exceeded .90 in the present study on all occasions. Concurrent and predictive validity for the word list were high, as evidenced by .80 correlations with the Letter Word and Word Attack subtests of the Woodcock-Johnson Psychoeducational Battery-Revised (Woodcock & Johnson, 1989). For the analysis, we used IRT scores based on estimates of each person's latent trait on word recognition skills as an indicator for word recognition ability. IRT estimates were scaled to have a mean of 0 and a standard deviation of 1.

### Rapid Naming

Denckla and Rudel's (1976) Rapid Automatized Naming Tests for Letters was administered in kindergarten. Rapid automatized naming letters were high-frequency lowercase letters (e.g., *a*, *d*, *o*, *s*, *p*). The stimuli consisted of five letters in a row, repeated 10 times in random sequences. The child was asked to name each letter as quickly as possible. The correct number of responses within 60 s was recorded. Test-retest reliability was .57 for kindergarten (reflecting variability in true change over this age range) and .77 for Grades 1 and 2. Children who did not know all five letters were not administered the test (Schatschneider et al., 2004). For the purposes of the current study, the scores obtained from April data collection were log-transformed and included in the analysis.<sup>1</sup>

Descriptive statistics based on the IRT scale on all of the measures are shown in Table 2. For phonological awareness, scores ranged from 1.22 *SD* below the mean to about 0.60 *SD* below the mean across the four time points in kindergarten. For word recognition, scores ranged from 0.98 *SD* below the mean to 0.77 *SD* above the mean across the eight time points during Grades 1 and 2.

### Analysis

The application of growth modeling with mixture components has been explored by other researchers (Nagin, 1999; Verbeke & LeSaffre, 1996); however, recent work introduced by Muthén (2000) and Muthén and Shedden (1999) has provided a much more flexible framework than previous models. General growth mixture modeling introduced by Muthén and colleagues provides technical advantages over conventional growth models by allowing greater flexibility in model specifications and assumptions. One of the theoretical assumptions of the conventional growth model is that the data come from a single population and that the single-population model accounts for all of the variation in the individual trajectories. As both the data and developmental theory suggest, however, there may be several heterogeneous subgroups within this population that require different sets of model specifications and assumptions. For example, as shown in Figure 1, although

<sup>1</sup> For the rapid naming variable, we combined the speed measure, RNL\_S (number correct/number of seconds) with total correct (RNL\_TR) to create TRNL (rapid naming), where  $TRNL = \log_2(RNL\_TR / RNL\_S + .1)$ .

Figure 1. Individual growth trajectories for word recognition development. The two colors represent two distinct growth profiles of reading development.

there may be two different groups of students with very different reading development trajectories, with the conventional growth modeling techniques it would be difficult to detect the misspecification of the model. With the conventional growth models, the estimation of growth is determined by a single collection of growth trajectories with a single vector of means and covariance parameter estimates for intercept and slope parameters. In contrast, growth mixture modeling allows the identification of different subgroups in the model that represent the different collections of reading development trajectories. Hypothetically, the kindergarten growth parameters for a group of students with high intercept (exit level at kindergarten) and growth may influence reading development in Grade 1 differently than for students with low intercept and growth in kindergarten. Accordingly, individuals with similar exit levels in kindergarten may belong to different subgroups with different rates of development. An accelerated growth rate of precursors in kindergarten may suggest that these students are qualitatively different from students with no significant growth during the same time period. Accelerated growth can also be interpreted as a higher aptitude for learning, which could have a greater influence on reading development in Grade 1. Additionally, one could hypothesize heterogeneity in the influence of covariates on the different developmental trajectories.

Growth mixture modeling generalizes conventional growth modeling by allowing heterogeneity of different subgroups in the population through the use of a categorical latent variable (Muthén, 2000, 2001; Muthén & Shedden, 1999). These categorical latent variables or latent classes can represent multiple groups with different developmental trajectories for which group membership is unknown but can be inferred from the data. Individuals are

allowed to be in one of  $K$  latent classes, each with characteristically distinct developmental profiles. Within a class, individual developmental trajectories are allowed to vary around this class profile. For each class  $k$ , continuous outcome variables  $Y$  are assumed to be normally distributed conditional on covariates  $x$ . The growth mixture model can be expressed as follows:

$$Y_{ik} = \nu_k + \Lambda_k \eta_{ik} + K_k x_{ik} + \varepsilon_{ik} \quad (1)$$

and

$$\eta_{ik} = \alpha_k + B_k \eta_{ik} + \Gamma_k x_{ik} + \zeta_{ik}. \quad (2)$$

Here,  $Y$  represents the repeated measures over fixed time points. The  $\eta_{ik}$  are random effects, and  $\Lambda_k$  represents time scores for the shape of the growth curves.  $K_k$  represents the effects of time-varying covariates, and  $\Gamma_k$  represents the effects of time-invariant covariates.  $\alpha_k$  represents the intercepts for  $\eta$  for latent class  $k$ . For the example we discuss,  $\alpha_k$  represents the different reading development trajectories for the different classes. The residual vectors  $\varepsilon_{ik}$  and  $\zeta_{ik}$  are assumed to have covariance matrices  $\Theta_k$  and  $\Psi_k$ , respectively.

The  $K$  trajectory classes are allowed to include variation in both intercepts and slopes in phonological awareness and word recognition. This framework, introduced by Muthén et al. (2002), Muthén and Muthén (2000), and Muthén and Shedden (1999), is much more wide ranging than the mixture models proposed by Nagin (1999), in which it is assumed that  $\Psi_k = 0$  and  $\Theta_k = 0I$ . A model proposed by Muthén (2000) provides more flexibility by allowing class-to-class variation of the covariance matrices  $\Psi_k$  and  $\Theta_k$ . This modeling specification is particularly important when determining

the number of latent class trajectories. Depending on how the degree of class invariance is specified, different values for model fit criteria will be obtained.

Estimated posterior probabilities for each individual's class membership are derived as follows. Define the latent class membership indicators  $c_{ik}$  to be 1 if individual  $i$  belongs to class  $k$ , and 0 otherwise. Then

$$p_{ik} = P(c_{ik} = 1 | y_i, \mathbf{x}_i) \propto P(c_{ik} = 1 | \mathbf{x}_i) f(Y_{ik} | \mathbf{x}_i). \quad (3)$$

In this study, the individual students were assigned to a class based on their highest estimated posterior probabilities. The posterior probabilities were computed for a given individual observation vector  $(y_i, \mathbf{x}_i)$ . In other words, for a given model, individual students' posterior probabilities were computed as a function of the model estimates and the individuals' values on observed variables.

To understand the composition of classes and also to provide stability in class membership, Muthén (2000) introduced a multinomial logistic regression model to represent the relationship between  $c$  (latent class variable) and  $x$  (covariate). The multinomial logistic regression for predicting class membership with a covariate can be expressed as follows:

$$P(c_{ik} = 1 | x_i) = \exp(\beta_{0k} + \beta_{1k}x_i) / \sum_{c=1}^K \exp(\beta_{0c} + \beta_{1c}x_i), \quad (4)$$

for  $k = 1, \dots, K$  where we constrain  $\beta_{0K} = 0$  and  $\beta_{1K} = 0$ , and where  $P(c_{ik} = 1 | x_i)$  is the probability of being in class  $c_{ik}$  conditioned on covariate  $x$ ,  $\beta_{0k}$  is the class intercept, and  $\beta_{1k}$  is the regression coefficient for the  $k$ th class on  $x_i$ , the covariate. The parameter estimates in the model are most easily interpreted by computing predicted class membership probabilities as a function of the covariate.

One of the advantages of this general latent variable modeling framework is that one can systematically explore the influence of precursor skills on later development. For example, students with rapid development of phonological awareness in kindergarten, despite their low performance at the entry level, may continually show rapid development in word recognition as well. In contrast, students with a low entry level and slow development of phonological awareness may not improve much in word reading when they enter Grades 1 and 2. Despite the similarities in initial appearance between these two groups of students, the students with slow development may be qualitatively different from the students with rapid development of phonological awareness. Also, the differences in students' developmental trajectories in kindergarten may differentially influence their later reading development.

### Model Selection and Model Fit

In growth mixture modeling, determination of the optimal number of groups that best represents the data is part of the model selection procedure. The best method for determining the number of classes or groups is still a topic of controversy. For the present study, we considered two statistical indices as well as the overall interpretability of the model based on class counts and substantive theory for model selection. For comparison of nested models with

the same number of classes, the usual likelihood ratio chi-square difference can be used. However, when comparing models with different numbers of classes, the likelihood ratio test may no longer be applicable, and other information criteria must be used. Although McLachlan and Peel (2000) suggested assessing the number of modes of a distribution using the kernel method to estimate the density function, one drawback to this approach is that when classes or the components are not sufficiently separated, the mixture distribution can look unimodal, thus failing to detect the actual number of modes (classes). Also, if the data have a skewed distribution, using a normal mixture model will not be appropriate for capturing the number of classes (McLachlan & Peel, 2000). We used the Bayesian information criterion (BIC) to compare model fit between non-nested models. For a given model, BIC is calculated as follows:

$$\text{BIC} = -2 \log L + r \log n. \quad (5)$$

Here,  $L$  is the value of the model's maximized likelihood,  $n$  is the sample size, and  $r$  is the number of parameters in the model. To determine the optimal number of classes for the best representation of the data, one compares BIC values across the different models, with smaller BIC values indicating a better model fit. However, the overall model selection is guided not only by BIC values but also by entropy indices (described in the next paragraph) and the interpretability of the chosen model, because the BIC tends to favor models with fewer classes (Wiesner & Windle, 2004).

Model selection was also guided by examining the reliability of the classifications via the estimated posterior probabilities of class membership for each individual (Muthén, 2000). The precision of the classification can be assessed by how well the students are being classified into each class. A reliable classification will require the student to have posterior probabilities that are very high for belonging to a single class and very low for belonging to all of the other classes. These probabilities determine the most likely class for each student. For example, a student's estimated probabilities may be .80 for Class 1, .15 for Class 2, .05 for Class 3, and 0 for Classes 4 and 5. A reliable classification is linked to the precision of probabilities in differentiating class membership. To check for precision in classification, one summarizes the probabilities into average posterior probabilities. For example, if the average posterior probability of Class 1 is .90, then one can conclude that the students being classified into Class 1 have, on average, very high probabilities of Class 1 membership. In addition, the quality of the classification is also summarized by the entropy measure (Muthén, 2000). Entropy is expressed as follows:

$$E_K = 1 - \{ \sum_i \sum_k [-p_{ik} \log(p_{ik})] / n \log(K) \}. \quad (6)$$

The expression  $E_K$  is bounded between 0 and 1. An entropy measure close to 1 is considered to be evidence of good classification.

### Analysis Procedure

In the first analysis stage, the development of phonological awareness in kindergarten was examined separately from the development of word recognition, because these represent two distinct (although developmentally sequential) linguistic processes.

The number of classes, as well as the type of growth trajectories, may vary from one grade to the next depending on the different types of latent growth trajectories present. Consequently, a four-group model might be best for representing the developmental profiles in kindergarten, but a five- or six-group model may be more appropriate for representing development in Grades 1 and 2.

Once the number of classes was determined for phonological awareness and word recognition development separately based on the BIC values, the entropy indices, and the interpretability of the model, the final model combining all three grades was selected. The purpose of these two separate analyses in the first stage was to provide a basis for selecting the final model that combined all 3 years of data. Although the developmental trajectories identified in the separate analyses were informative, the overall goal of the study was to find the best representation of data using all three grades. The final model selection was then guided by class counts and the overall model fit.

For the final model, we checked the overall model fit and the quality of the classification by examining how closely the estimates matched the observed data. One way to check this is to compare the estimated mean curve with the observed trajectories of individuals or the observed mean curves based on individual estimated conditional class probabilities. For this technique, we assigned individuals to classes based on the estimated posterior probabilities and then compared the individual trajectories with the estimated mean trajectory (Bandeén-Roche, Miglioretti, Zeger, & Rathouz, as cited in Muthén, 2000). Indication of a good model fit requires close alignment between the individual trajectories and the estimated mean trajectory.

For the present study, we used all 12 time points to investigate reading development across three grade levels (kindergarten, first, and second). For kindergarten, the IRT scale scores on phonological awareness from four different time points (October, December, February, and April) represented reading development. For Grades 1 and 2, we used the IRT scale scores on word recognition spanning 2 years with eight time points to represent continual reading development.

Results

Initial Model Selection Using Two Separate Analyses

Prior to identification of developmental profiles representing all three grade levels, we conducted preliminary analyses for each precursor (phonological awareness) and reading skills (word recognition) separately. First, models with between two and six classes were fit to the longitudinal phonological awareness data from the kindergarten portion of the data. As Table 3 presents, although the four-class model had the lowest BIC value, upon further examination of the class proportions for the four-class model, we determined that the four-class model lacked distinction between the different classes and was difficult to interpret, as shown in Table 4. Given the minimal difference in the entropy values between the four-class and the five-class model, the five-class model was finally chosen for interpretability purposes.

The estimated mean growth curves representing the five different developmental profiles in kindergarten are shown in Figure 2. As Figure 2 illustrates, PA 1 students represented the lowest

Table 3  
*BIC and Entropy Values for Kindergarten Models*

Class	BIC	Entropy
2	1,380.66	0.83
3	1,369.44	0.75
4	1,358.15	0.74
5	1,370.02	0.70
6	1,382.06	0.73

Note. BIC = Bayesian information criterion.

performing group. The estimated means and the standard errors for intercepts and slopes for the five-class model are presented in Table 5. As shown in Table 5, the mean of PA 1 students' phonological scores at the end of kindergarten was about 1.55 SD below the mean, compared to about 1.07 SD below the mean for PA 2 students and 0.26 SD below the mean for PA 3. Both the PA 4 and PA 5 students performed higher, with 0.10 and 1.14 SD above the mean than the overall average for phonological awareness, which was 0.60 SD below the mean at the end of kindergarten. The slope estimate for PA 1 students was 0.03, representing flat trajectory, compared to 0.14 for PA 2, 0.40 for PA 3, 0.27 for PA 4, and 0.34 for PA 5. As shown in Figure 2 and Table 5, PA 1 students started out with low performance in phonological awareness and exhibited no significant improvement throughout the entire kindergarten year. Given the lack of growth during the year, this group of students would be expected to be most at risk for developing reading difficulties in later grades. The estimated means for the slope and intercept for the five-class model are presented in Table 5 and illustrated in Figure 3.

Next, a separate analysis was conducted to fit the word recognition data from Grades 1 and 2. As shown in Table 6, after evaluating different numbers of models using BIC and entropy indices, we found the five-class model to be the best in terms of fit and interpretability. There was a significant decrease in the BIC values between the four-class and the five-class models, however BIC values started to level off after the five-class model. Also, the difference in entropy was minimal across five-class, six-class, and seven-class models. The estimated mean growth curves for the five-class model are shown in Figure 3. After evaluating the BIC values and entropy indices, we determined that the five-class model was the best in terms of fit and interpretability.

As shown in Table 7 and Figure 3, WR 1 had the lowest intercept and slope in the five-class model. The average score for word recognition at the end of Grade 2 was 0.77 SD above the mean. For WR 1 students, the average score was 0.95 SD below the mean, which was significantly lower than the next low performing group (WR 2), which had an average score of 0.46 SD above the mean. Students in WR 1 were thus characterized as the students who were at risk for reading difficulties.

Final Model: Combining Models of Phonological Awareness and Word Recognition

The selected five-class model for phonological awareness and the selected five-class model for word recognition were next combined to allow growth modeling for all 3 years. In the com-

Table 4  
*Class Counts and Proportion of Students in the Kindergarten Four-Class Model*

Variable	Class 1	Class 2	Class 3	Class 4
Class count	229	20	131	31
Proportion of total sample	56	5	32	7

combined analysis, as shown by the path diagram in Figure 4, development of phonological awareness in kindergarten was represented by Intercept 1 and Growth 1, development of word recognition was represented by Intercept 2 and Growth 2, classes were represented as latent variables C1 and C2, and rapid naming measured at the end of kindergarten was also added in the model as a covariate for class membership. Given previous research on phonological awareness and rapid naming, we believed that although there is significant overlap between these two skills, they contribute independently to reading and that rapid naming can be considered an etiologically distinct source of variance in reading outcomes (Petrill, Deater-Deckard, Thompson, DeThorne, & Schatschneider, 2006a).

As an initial step in the analysis, we considered the model in which all students stayed in the same developmental trajectory throughout all 3 years, as shown in Table 8. However, in the final model, to provide a more realistic representation of the data, students were allowed to change class membership during the transition from kindergarten (phonological awareness) to Grades 1 and 2 (word recognition). For example, a student classified as PA 1 based on phonological awareness development was allowed to

Table 5  
*Intercept and Slope for Five Phonological Awareness Development Profiles*

Profile	Intercept <i>M</i> ( <i>SE</i> )	Slope <i>M</i> ( <i>SE</i> )
PA 1	-1.55 (0.26)	0.03 (0.04)
PA 2	-1.07 (0.23)	0.14 (0.06)
PA 3	-0.26 (0.19)	0.40 (0.16)
PA 4	0.10 (0.15)	0.27 (0.04)
PA 5	1.14 (0.31)	0.34 (0.09)

Note. PA = phonological awareness.

progress to a WR 2 or to a WR 3 profile based on word recognition development. By allowing change in class membership, we were able to determine which students stayed in the same developmental trajectories throughout 3 years and which students changed their class membership. The assumption was that if students did stay within the same class throughout the three grades, then the kindergarten classification should correspond directly to Grade 1 and Grade 2 classification. To check for this assumption, we fitted the observed growth curves in Grades 1 and 2 to the estimated mean curves from the kindergarten classes. As illustrated in Figure 5, the observed growth curves in Grades 1 and 2 did not fit the estimated mean curve represented by the dark solid line. Subsequently, we determined that not all PA 1 students corresponded directly to WR 1 students, and not all PA 2 students corresponded directly to WR 2 students, and so on. Instead, as expected, some students did move into other developmental trajectories in Grades 1 and 2. To

Figure 2. Estimated mean growth curves for the five-class model representing the phonological awareness (PA) in kindergarten.

Figure 3. Estimated mean growth curves for the five-class model representing the word recognition (WR) development in first and second grades.

represent this transition from kindergarten to Grades 1 and 2, we allowed for transitional classes in the final model specification.

On the basis of class count, entropy, and model fit, the resulting 10-class model included several different transitional patterns in class membership from kindergarten to Grades 1 and 2. Table 9 describes the 10 different developmental profiles identified in the final model and the class counts based on their estimated class probabilities. The parameter estimates and their standard errors are shown in Table 10 and Figure 6 illustrates the estimated mean curves for phonological awareness and word recognition development. For example, in Figure 6, Class 1 represents the students with developmental profiles corresponding to PA 1 and WR 1, and Class 3 represents the students with developmental profiles corresponding to PA 2 and WR 3.

Table 6  
*BIC and Entropy Values for Grade 1 and 2 Models*

Model	BIC	Entropy
Two-class	2,260.08	0.76
Three-class	2,297.29	0.74
Four-class	2,273.16	0.73
Five-class	2,245.80	0.78
Six-class	2,236.49	0.79
Seven-class	2,233.74	0.82

Note. BIC = Bayesian information criterion.

As illustrated by Figure 6, in the final 10-class model, Class 1 (PA 1 transition into WR 1) students again represented the students who were at risk for reading difficulties because these students' trajectories remained flat. The Growth 1 estimates, which represented the slope for phonological awareness in the final model, ranged from 0.05 (representing flat trajectory) to 0.33 (significant growth). Similarly, for Growth 2, the estimates ranged from 0.03 to 0.27. As shown in Table 10, Class 1 students' reading development trajectories remained flat across all 3 years at 0.05 and 0.03 for Growth 1 and Growth 2, respectively. Class 2 students who, based on the slope and intercept estimates, started out initially at about the same level on phonological awareness skills as Class 1 students, continued to show growth on both phonological

WR 2	0.46 (0.08)	0.27 (0.01)
WR 3	1.27 (0.08)	0.26 (0.01)
WR 4	2.03 (0.14)	0.51 (0.02)
WR 5	1.73 (0.07)	0.15 (0.01)

Note. WR = word recognition.

awareness (Growth 1 = 0.10) as well as word recognition (Growth 2 = 0.23) in contrast to Class 1 students, who showed essentially no growth (Growth 1 = 0.05 and Growth 2 = 0.03) during the same time period. As shown in Table 9, the groups on the diagonal represent the students who remained within the same class across the three grades. The students transitioning into different classes from their original classification in kindergarten are represented by Class 3 (PA 2 into WR 3), Class 4 (PA 3 into WR 2), Class 6 (PA 3 into WR 4), Class 7 (PA 4 into WR 3), and Class 9 (PA 4 into WR 5). The proportion of students that transitioned from one developmental profile to another is shown by the italicized entries in Table 9.

As Table 9 shows, there were only 8 students grouped into Class 4. This class comprised students who were originally classified as PA 3 in kindergarten and who subsequently moved into WR 2 in Grades 1 and 2, which were only a few students. The results also indicated that none of the students transitioned into or out of Class 1. This finding suggests that students in Class 1 were very homogeneous and were indeed the students who we considered to be most at risk for reading difficulties in later grades.

We also investigated the relationship between the growth parameters in kindergarten and the growth parameters in Grades 1 and 2. Only the relationship between word recognition growth and phonological awareness intercept was shown to be statistically significant. In other words, the rate of development in Grades 1 and 2 was directly related to the status of phonological awareness at the end of kindergarten.

#### Evaluation of Model Fit for the 10-Class Model

In order to determine how well this 10-class model fit the data, we plotted a random sample of the observed individual trajectories against the model-estimated mean trajectories. Each individual student was assigned to his or her respective class based on the student's weighted individual class probabilities. A random sample of individual trajectories (observed, not estimated) was plotted

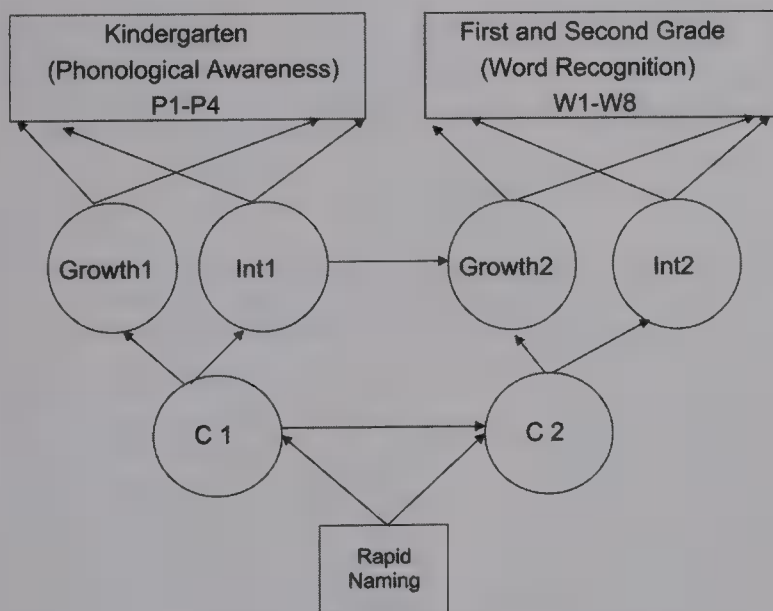

Figure 4. Path diagram for phonological awareness (P) and word recognition (W) combined. Int = intercept; C = class.

Table 8

Five-Class Model Specification

Kindergarten	Grades 1 and 2				
	WR 1	WR 2	WR 3	WR 4	WR 5
PA 1	Class 1	Class 2	Class 3	Class 4	Class 5
PA 2					
PA 3					
PA 4					
PA 5					

Note. WR = word recognition; PA = phonological awareness.

against the estimated mean trajectories for each class for comparison. Except for signs of minor discrepancy in Class 5, all of the observed individual trajectories looked homogeneous around the estimated mean curves (see Figure 7). Class 5 represented the students who were classified as PA 3 in kindergarten and remained in WR 3 in Grades 1 and 2. Additionally, the entropy for the 10-class model was 0.76, which signified moderate to high clarity in the classification.

#### Differences in Rapid Naming

Performance on rapid naming, measured at the end of kindergarten, was included in the model as a covariate for class membership. As explained in the Method section, the significance of this covariate was examined by including a multinomial logistic regression component in the final model. The logistic regression plot shown in Figure 8 illustrates the differential effect of rapid naming on the probability distribution function of the 10 classes. Figure 8 shows that the probability of belonging to Class 1 was much higher when performance on rapid naming was low. Conversely, as illustrated in Figure 8, as the score on rapid naming increased, the probability of an individual belonging to Class 1 decreased significantly. This finding qualitatively differentiated students who entered school with comparably poor phonological awareness (e.g., PA 1 and PA 2 students) but progressed to very different outcomes. The results indicate that students who exhibited no significant improvement in phonological awareness in kindergarten were also the students with the lowest rapid naming skills at the end of kindergarten.

#### Differences in Ethnicity

To help characterize the Class 1 students, we examined the relationships among gender, ethnicity, SES, and class membership using the chi-square test. There was a statistically significant difference in the proportion of minority students in Class 1 compared to other classes. The proportion of minority students in Class 1 was 51% compared to only 31% in other classes ( $p = .01$ ). SES and gender were not statistically significant ( $ps = 1.0$  and  $.34$ , respectively).

#### Discussion

The purpose of this study was to introduce growth mixture modeling as a new approach to the identification of heterogeneous

Figure 5. Word recognition development based on kindergarten classification.

Table 9  
*Class Specifications and Class Counts for the 10-Class Model*

Kindergarten	Grades 1 and 2				
	WR 1	WR 2	WR 3	WR 4	WR 5
PA 1	Class 1: 45 (11%)				
PA 2		Class 2: 63 (15%)	Class 3: 77 (19%)		
PA 3		Class 4: 8 (2%)	Class 5: 56 (14%)	Class 6: 36 (9%)	
PA 4			Class 7: 20 (5%)	Class 8: 8 (14%)	Class 9: 30 (7%)
PA 5					Class 10: 18 (4%)

*Note.* Values represent *n* and percentage for each class. The italicized entries represent the five classes that changed class membership between grades. WR = word recognition; PA = phonological awareness.

reading development profiles with data from a 3-year longitudinal study of reading precursors (e.g., phonological awareness) and outcomes (e.g., word recognition). Using this technique, we have identified a group of students with a distinct developmental pattern who are most at risk for reading difficulties. Although further studies are required to validate this group of students as potentially reading disabled, we have empirically identified a group of students with reading difficulties using a new approach.

Application of growth mixture modeling in this study highlights two important issues related to reading development research. First, as shown in previous research, this study empirically demonstrated the multidimensional continuity of the distribution of reading ability (Shaywitz et al., 1992). The results from this study indicate that developmental profiles identified in kindergarten are directly associated with reading development in Grades 1 and 2. The students identified as having difficulties acquiring phonological awareness skills in kindergarten exhibited slower developmental patterns in word recognition skills in subsequent years of the study. Specifically, although students in the lowest performing trajectory class were allowed to change membership with potential for improvement, in fact, nearly all of the students identified as the lowest performing group in kindergarten stayed in the same developmental trajectory throughout the 3 years. The use of growth mixture models to identify and classify students with reading difficulties minimizes anomalies and unfairness that are consequences of using an arbitrary cutoff for classification purposes. Using growth mixture models, researchers can circumvent the

problems associated with arbitrary classification of students as reading disabled.

Previous research has shown (Francis, Shaywitz, Stuebing, Shaywitz, & Fletcher, 1994), and the results from this study support the notion, that reading difficulties are best characterized by deficits in prerequisite skills that lead to deficits in reading development, rather than by a lag in reading development. Identification of a group of students with persistent deficits over the 3-year period suggests that unless the students acquire the necessary prerequisite skills, they will continue to lag behind. This finding underscores the need for early identification and interventions specifically targeting deficit skills. Reconceptualizing the identification of reading difficulties using longitudinal measures stimulates further questions regarding the implications of early assessment practices and suggests possible directions for future research in this area. Although there has been considerable debate surrounding the validity of using the Dynamic Indicators of Basic Early Literacy Skills to monitor reading progress, more than 40 states in Reading First schools are now currently using the Dynamic Indicators of Basic Early Literacy Skills to screen Kindergarten–Grade 3 students for potential reading difficulties. Some states are also using the Phonological Awareness Literacy Screening Tests as an alternative tool. Given the lack of consensus on the most appropriate measures for monitoring reading progress, implementation of the proposed identification model will require further research in the area of assessment development. In addition, as researchers consider the practicality of implementing the reading progress monitoring model, the minimum data requirement for reliable classification must also be taken into consideration. As previous research has shown (Rogosa, 1988; Willett, 1988), it becomes difficult to obtain reliable estimates of the correlation between change and initial status with only two assessment data points due to measurement error in initial status.

Second, the findings suggest that the students with reading difficulties may in fact consist of various subgroups or subtypes, each with distinct developmental profiles manifesting from differences not only in outcomes but also possibly in etiology. As shown in the development of phonological awareness in kindergarten, although Class 1 and Class 3 students looked similar in terms of their initial status, rates of development differed significantly between these two groups of students, and, ultimately, this difference in the rate of development manifested a greater gap in students' reading development. Given the significant relationship

Table 10  
*Estimated Means and (Standard Errors) of Intercepts and Growth Parameters for the 10-Class Model*

Class	Intercept 1	Growth 1	Intercept 2	Growth 2
1	−1.50 (0.07)	0.05 (0.02)	−1.05 (0.09)	0.03 (0.04)

9	0.15 (0.07)	0.30 (0.02)	1.82 (0.05)	0.17 (0.02)
10	1.09 (0.20)	0.33 (0.05)	1.82 (0.05)	0.17 (0.02)

Figure 6. The 10-class model: estimated mean growth curves for phonological awareness (PA) and word recognition (WR).

between class membership and rapid naming, the results suggest that rapid naming and phonological skills are good predictors of subsequent reading development, as was previously shown in other studies (Petrill, Deater-Deckard, Thompson, DeThorne, & Schatschneider, 2006b; Torgesen, Wagner, Simmons, & Laughon, 1990; Walsh, Price, & Gillingham, 1988). Identification of students with poor developmental profiles in reading is a multivariate problem, and a univariate approach is inadequate for studying the complexity of the problem (Fletcher, Francis, Rourke, Shaywitz, & Shaywitz, 1992; Francis et al., 2005). Performance on the rapid naming test in kindergarten was a key indicator for differentiating the different reading development profiles in this study, but other relevant measures such as expressive vocabulary, verbal memory, and story recall should be explored and studied in detail. Although previous studies on reading disability subtypes have used multivariate clustering techniques to identify subtypes, these have been limited to single time point data (Morris et al., 1998). A growth mixture model may provide an alternative approach to identifying reading disability subtypes.

With different developmental profiles of reading, deficits in specific areas can be easily identified, and appropriate instructional strategies can target specific problem areas. As Berninger and Abbott (1994) stated, "The diagnosis of learning disability often is not tied to well-specified deficits clearly linked to instructional interventions" (pp. 166). Consequently, as a large-scale field study

conducted by Haynes and Jenkins (1986) revealed, reading instructional programs often are not linked to meet the needs of the characteristically different individual students. Identification of distinct developmental profiles may provide ways to differentiate treatment based on different treatment responses. With an effective identification system linked to appropriate remediation strategies, students will be able to receive supplementary instruction that is appropriately targeted for maximum benefit. As previous research has suggested (Fletcher, Francis, Morris, & Lyon, 2005; Torgesen et al., 2001), early identification is key to successful remediation programs. It is also important to recognize that, in accordance with the RTI model, identification is only the first stage in the intervention process. For successful remediation and prevention, early screening and appropriate intervention have to be followed up with progress monitoring.

This study also found that the percentage of minority students in Class 1 was higher than in other classes. This increased representation of minorities in Class 1 reflects the fact that minorities are at increased risk for reading problems. A report from the National Research Council (1998) suggested that "children from poor families and children of African American and Hispanic descent are at much greater risk of poor reading outcomes" (p. 27). Teasing apart the relationship of external factors and reading achievement is complicated by inadequate indicators of SES such as the self-report data that we used in our study. One of the limitations of this

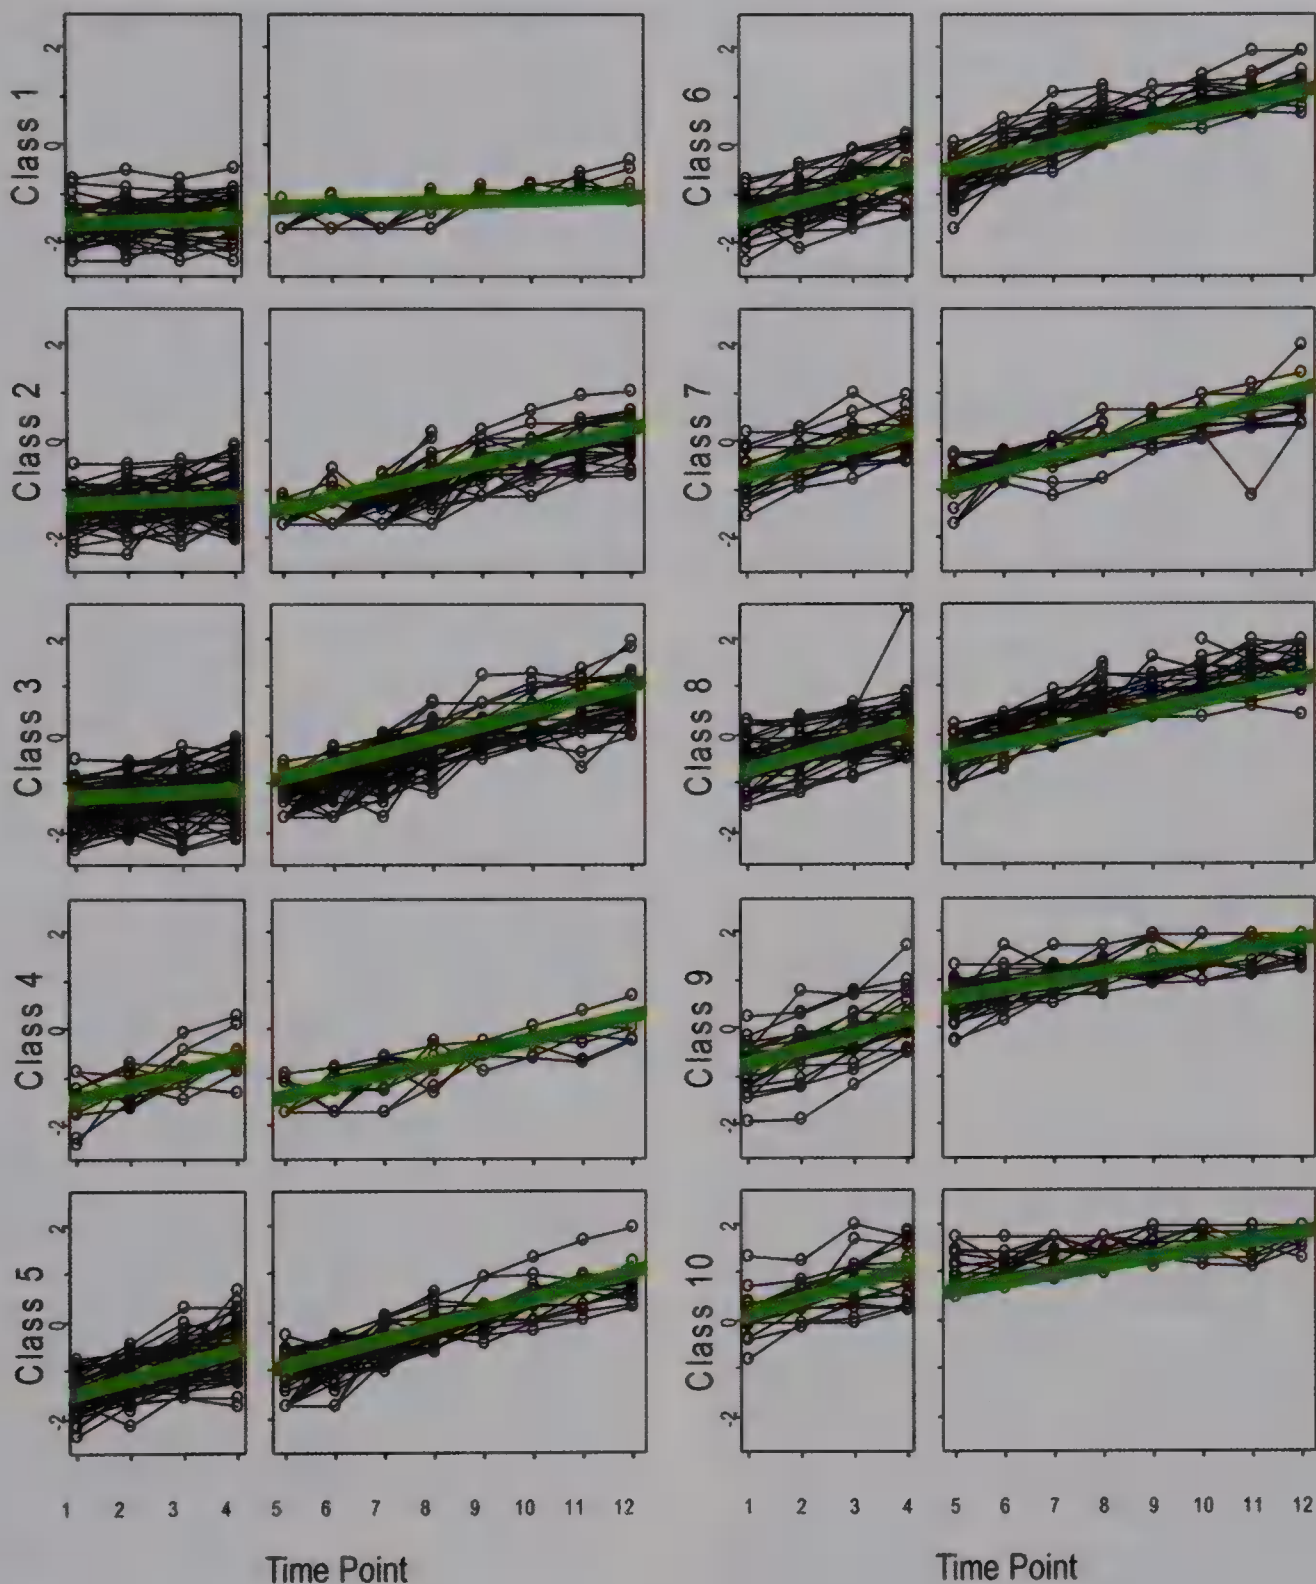

Figure 7. Observed individual growth trajectories with estimated mean growth trajectories for the 10-class model.

study is that, although the identification of Class 1 students was associated with minority status, given the limited information on student background, the characterization of students with potential reading failure was insufficient.

Another limitation of our findings is the relatively restricted measure of word recognition and the lack of a reading comprehension measure. We found that the correlation was quite high between our word recognition measure and the word attack

measure, as measured by the Word Attack subtest of the Woodcock-Johnson Psychoeducational Battery-Revised (Woodcock & Johnson, 1989). At the end of Grade 1, the correlation was .78 between our word reading recognition measure and Woodcock-Johnson Word Attack. At the end of Grade 2, the correlation was .71. Given the importance of reading comprehension skills in reading development, replication of this study with the inclusion of a comprehensive word reading

Figure 8. Multinomial logistic regression of class regressed on rapid naming score.

measure that includes nonsense words as well as reading comprehension is warranted.

Another important factor omitted in the analysis was school-level variability. Given there were only three schools in the study, systematic exploration of school effects on student reading outcomes was not possible with this current study sample. The fact that all three schools came from one single district with a common approach to reading instruction should minimize the potential school-level variability due to instruction.

Finally, given the recent findings in behavioral genetics studies (Byrne et al., 2002; Harlaar, Spinath, Dale, & Plomin, 2005; Petrill et al., 2006b), it will be important to consider environmental factors as well as genetic differences in early readers when examining differential treatment effects. Petrill et al. (2006b) found that environmental influences were substantial in explaining the individual variances in phonological awareness, however rapid naming seemed to be significantly influenced by genetic variance. For successful remediation, it is important for future studies to consider various individual and environmental factors to help characterize the different reading development profiles.

# The Effects of Tasks on Integrating Information From Multiple Documents

Raquel Cerdán  
Catholic University of Valencia

Eduardo Vidal-Abarca  
University of Valencia

The authors examine 2 issues: (a) how students integrate information from multiple scientific documents to describe and explain a physical phenomenon that represents a subset of the information in the documents; and (b) the role of 2 sorts of tasks to achieve this type of integration, either writing an essay on a question requiring integration across texts or answering shorter intratext questions that require students to integrate information within a single text, while superficial and deep comprehension measurements are obtained. Undergraduate students answered 1 of the 2 types of questions, and their reading times were recorded. Half of the sample thought aloud. Results showed that the integration question increased integration and decreased the processing of isolated units of information, which enhanced deep learning, whereas no differences between the 2 sorts of tasks on memory recall were apparent. This research also provides evidence for the discrepancy between training and posttraining effects (R. A. Schmidt & R. A. Bjork, 1992).

**Keywords:** multiple documents, integration, task effects, thinking aloud, posttraining and deep learning effects

Nowadays, students are frequently exposed to different and multiple sources of information with which they may be asked to perform a variety of tasks such as writing essays, answering comprehension questions, or locating specific units of information. Let us take the example of a science teacher in a high school who gives a group of students a set of reliable documents on bacteria resistance to antibiotics for students to learn some specific issues included in the documents, such as how bacteria resist the effects of antibiotics and which biological mechanisms explain this phenomenon and its transmission to other bacteria. As the documents have been written by different authors with different purposes in mind, the information they contain may partially overlap across texts. At the same time, a given passage will include specific aspects of the problem not considered in a different passage. Additionally, the documents might contain information different from that of the specific interests of the teacher (e.g., the consequences of bacteria resistance or solutions for the problem).

Therefore, the first job for the student is to select and process the pieces of information relevant to the specific issues proposed. He or she also has to recognize when an idea in a document has been presented in a different document, though it may be discussed using different words, so that a reinstatement process occurs. He or she also has to learn that a piece of information from a document complements another piece from a different document and decide what sort of relationship between the two pieces can be estab-

lished. Finally, the reader has to organize all of the selected information to give a coherent answer to the teacher's question. Thus, integrating information from multiple documents is a highly demanding task that involves more processes than those involved when just reading a single text.

Much research on integration of information from multiple documents has been conducted with texts addressing a controversial historical event presented from different and opposing points of view (Britt, Rouet, Georgi, & Perfetti, 1994; Rouet, Britt, Mason, & Perfetti, 1996; Rouet, Favart, Britt, & Perfetti, 1997; Wineburg, 1991, 1994; Wolfe & Goldman, 2005). In this research, models of different situations were formed from the texts, and the students' task was to compare the documents and undertake some sort of reasoning from the models. This process involved constructing a *document model* that consisted of an *intertext model* representing the relationships among the different texts and among a text and elements of the situation (e.g., the source information or rhetorical goals), and a *situations model*, that is, the situations construed from each text and multiple interrelated situations (Perfetti, Rouet, & Britt, 1999).

In this article, in contrast, we are dealing with a different type of integration of information from multiple documents, that is, the description and explanation of a physical phenomenon created by putting together a subset of information from documents. This sort of integration may not need the construction of such a complex document model, a conclusion pointed out by Perfetti et al. (1999). According to these authors, whereas tasks and contexts that orient readers toward the issue of what was said by whom (i.e., comparison among documents) may involve the construction of a complex document model in which intertext and situations models can be distinguished, tasks and contexts that address the issue of what happened or how this could be explained may involve the construction of a single and simpler situation model. Students' success in this task would primarily depend on selecting, processing, and integrating relevant units of information from the documents. This

simpler integration process has received less attention in the research, and it is this sort of integration that we explore in this article.

The science teacher we are imagining should decide which sort of task is more helpful to students in order to reach their goals. A common approach is to facilitate the student's job as much as possible. However, some authors have demonstrated that conditions that make reading more effortful are more beneficial to learning than are less demanding conditions, though they make no difference to superficial comprehension measures such as text recall. For example, McNamara and colleagues (McNamara, Kintsch, Songer, & Kintsch, 1996; McNamara & Kintsch, 1996) found that less coherent text improved the reader's inferences but not recall. Mannes (Mannes, 1994; Mannes & Kintsch, 1987) found that readers performed better on a problem-solving task when an introductory outline did not match the text well.

Following these ideas, our goal in this research was twofold. First, we were interested in studying the processes of how students integrate information from multiple scientific documents. Second, we wanted to test whether asking students to answer a question that requires them to integrate information across documents is more beneficial in terms of deep learning than dividing the task into smaller intratext questions that may facilitate the student's performance on the task and recall of information but hinder integration across documents. Before getting into the specifics of the research, we would like to highlight important theoretical questions about the two issues mentioned previously, that is, the processes to integrate information from multiple documents and how specific tasks may be more effective than others in fostering such integration.

### Processes to Integrate Information From Multiple Documents

Integrating information seems to be one of the central processes in reading multiple documents, as it helps in constructing a coherent mental representation from different sources. To create coherence in his or her mind, the reader has to undertake some mental activity to establish connections among different units of information from the different texts. In the context of learning from a single text, this connecting process is called *inference making*, and its activation results in the construction of a coherent mental representation (Goldman, 1997; Kintsch, 1998). On-line evidence for integration processes when reading a single text was provided by Coté, Goldman, and Saul (1998), who found that the number of times sentences were accessed was a strong predictor of students' understanding.

In a context related to our study, Rouet, Vidal-Abarca, Bert-Erboul, and Millogo (2001) also found behavioral on-line evidence for integration processes being induced by comprehension tasks. They asked undergraduate students to search a 35-paragraph text in order to answer high- or low-level questions. High-level questions required the students to process and connect dispersed units of information in the text, whereas low-level questions only required the location of very specific textual units. The authors observed that whereas high-level questions promoted a review-and-integrate search pattern (i.e., the students reviewed more paragraphs of the text and answered the questions more times), low-level questions triggered a locate-and-memorize search pattern,

which was apparent in the search for specific pieces of information and in locating and memorizing them to give their answers. In another study, Cerdán, Vidal-Abarca, Martínez, Gilabert, and Gil (2007) found that those patterns were related to differences in learning from text, as we explain in the following section.

Mannes and Hoyes (1996) found behavioral correlates in terms of reading times for the integration process. They conducted three experiments in which students first studied an outline of an expository text which was either similar to or different from the text and then read the complete text, so that when students encountered an idea in the text that they had studied in the outline, the idea was reinstated and integrated with the text information. Mannes and Hoyes found that readers who were given the different outline built a richer domain representation of the text content compared with those who had read the similar outline, though the former task was more demanding than the latter. They also found on-line evidence for the advantage of the different outline. Students who had read this outline spent more time reading text ideas previously studied in the outline than those who had read the similar outline. This finding means that students in the different outline condition employed more cognitive resources to integrate the two sources than did those in the similar outline condition, and that this effort was responsible for the learning effects.

Goldman (2004) and other colleagues investigated students' strategies when reading multiple science documents that differed in reliability in order to explain a physical phenomenon (the eruption of Mount St. Helens). After reading, students wrote an essay explaining the phenomenon and ranked the reliability of the documents. It was found that good learners (i.e., those with significant gains from the text topic when comparing their knowledge before and after reading) produced more self-explanations on relevant documents and concentrated those self-explanations on regions of interest (i.e., text regions with information relevant to the criterial task) compared with poor learners. Moreover, poor learners seemed not to distinguish good from bad information in terms of the criterial task.

In summary, integration processes can be observed when recording reading behaviors with measurements such as rereading text information, slowing reading, or concentrating on information relevant to the task. These processes can be enhanced with tasks that make students connect different units of information. These tasks may require more effort, but in compensation they produce more learning than less demanding tasks. In the following section we explore this issue more deeply.

### Tasks to Promote Integration From Multiple Documents

Schmidt and Bjork (1992) reviewed some counterintuitive phenomena associated with the notions of training, performance, and learning. They presented evidence showing that experimental conditions that facilitate performance during training can be detrimental in the long term and, conversely, that manipulations that degrade the speed of acquisition or increase difficulty can nevertheless support the long-term goals of training. Therefore, according to these authors, learning should not be indexed by the improvements in skills across practice but should be measured as the level of posttraining performance. Additionally, making the process of learning more effortful may be helpful in terms of deep

learning. These two conclusions can also be applied to comprehension and learning from text.

Cerdán et al. (2007) had college students study a long science text by reading it and answering either high- or low-level questions with the text available; students' performance when answering the questions was recorded. Two days later the students were tested on two poststudy measurements that differed in the level of learning they were capturing (i.e., memory recall, inference, and problem solving). Students in the high-level questions condition scored higher than those in the low-level questions condition on the test measuring inferences and problem solving, though no differences were apparent on the memory recall test. Differences in the deep level of learning can be explained because of the search pattern when answering the two sorts of questions. Thus, whereas students answering high-level questions reviewed and connected more relevant units of information (i.e., a review-and-integrate search pattern), students answering low-level questions concentrated on locating isolated textual units (i.e., a locate-and-memorize search pattern). Hence, although high-level questions required the students to devote more effort to the task, they helped the students integrate text information, which is apparent when measuring deep but not superficial levels of comprehension.

In the context of the integration of information from different documents, Wiley and Voss (1999) manipulated readers' mental activity by instructing students to write arguments, narratives, summaries, or explanations when reading either a set of documents or the same information presented as a textbook chapter. In two experiments they found that writing arguments was more effective for making inferences and transforming information than the other conditions, but no differences were apparent when the test involved repeating information. Writing arguments made students establish more connections among ideas, particularly causal connections, which produced a more integrated situation model of the events described in the documents.

In summary, tasks that induce students to integrate ideas across a long text or a set of documents benefit making inferences and solving problems, even though such tasks require more effort. However, those benefits are not apparent with superficial learning, as this level of learning can be achieved with less cognitive effort. Thus, when measuring performance in the short term, no differences among more and less demanding tasks may appear, but these differences may be apparent with measures that capture a deep level of learning.

### Objectives and Hypothesis for This Study

Earlier we summarized our main purposes for this study. First, we wanted to deepen our understanding of the mental processes responsible for enabling integration from multiple sources and to find behavioral correlates for these processes. Second, we wanted to test the effectiveness of two sorts of tasks to induce integration and learning from multiple documents. The tasks were either (a) to write an essay on a broad or intertext question that involved selecting, processing, and combining a subset of information across the documents; or (b) to answer more narrow intratext questions covering the same information. These intratext questions induce less integration as they are answered individually and each is based on only one text.

To accomplish these goals, we selected three texts on the general topic of bacteria resistance to antibiotics from which students had to select, process, and combine a subset of information on a specific issue included in the documents, that is, mechanisms by which bacteria become resistant and how this resistance can be transmitted to other bacteria. Each of the texts partially presented this subtopic and also included irrelevant information. Thus, integration across relevant units of information coming from each document could take place. Only the student who extracted and combined the relevant units of information in each text could construct a coherent representation of the subtopic. In contrast, readers failing to extract and connect the relevant pieces of information in each text would not be able to construct an accurate and coherent representation of the main issue presented across the documents.

We hypothesized that the task of writing an essay on a broad or intertext question would be more effective to fostering the integration of relevant pieces of information across documents than answering the intratext questions. The former task would make students connect many of the ideas relevant to the task and to process them together, which would be apparent in both the on-line processing measures and the final learning result. However, no differences between the two sorts of tasks were predicted, whether on task performance or on memory recall, as the students would select the relevant information at the same level independently of the type of task.

We used the think-aloud method to obtain convergent on-line evidence for our experimental hypothesis. The think-aloud method has been demonstrated to reflect what is available in working memory, accessible to consciousness, and codable in language (Ericsson & Simon, 1980, 1993), and would therefore be indicative of which mental processes and content are responsible for how students perform and learn from a specific task. Indeed, there has been a growing use of this method in text comprehension research to obtain strategic data (i.e., Coté & Goldman, 1999; Goldman & Durán, 1988; Magliano, Trabasso, & Graesser, 1999; Pressley & Afflerbach, 1995; Trabasso & Magliano, 1996).

Thus, using a think-aloud procedure should provide valuable data on the processes and strategies that occur during comprehension, and the validity of these data would increase if convergence with other kinds of data were provided (Long & Bourq, 1996; Whitney & Budd, 1996). Indeed, converging evidence for the conclusions drawn from protocol data has been provided (Magliano & Millis, 2003; Suh & Trabasso, 1993; Trabasso & Magliano, 1996; Trabasso & Suh, 1993). Additionally, using the think-aloud methodology as one part of a converging evidence strategy was presented in Magliano and Graesser's (1991) three-pronged approach to comprehension research. Magliano et al. (1999) also used converging measures of think-aloud protocols and reading times. They correlated think-aloud content with silent-reading times and found a relationship between the increase or decrease in sentence-reading times and the type of text-processing strategy.

Nevertheless, an important controversy has arisen regarding the degree to which using a think-aloud procedure interferes with performance and learning when compared with silent-reading conditions. Ericsson and Simon (1980, 1993) argued that participants can generate verbalizations subordinated to task-driven cognitive processes without changing the sequence of their thoughts and slowing down only moderately due to the additional verbalization.

They insisted, providing substantial evidence based on research, that if participants are asked only to verbalize thoughts per se (*Type 1 and 2 verbalizations*), no interference effects will be apparent. Nevertheless, some experiments request participants to provide reasons, justifications, and elaborations (*Type 3 verbalizations*). In such cases, some studies found that verbalization affected performance (Ericsson & Simon, 1993), but the ways in which it did so were diverse, in some cases increasing performance and learning and in other cases hindering both.

This discrepancy is also present in text comprehension think-aloud studies with college students or adult readers. There is evidence that having students verbalize their thoughts while performing a task creates no difference compared to a silent-reading condition. Two studies with adult readers found no differences in comprehension between readers who stopped to give think-aloud comments and those who read silently (Crain-Thoreson, Lippman, & McClendon-Magnuson, 1997; Fletcher, 1986). Contrary to these results, there is also evidence that thinking aloud may hinder comprehension and learning from text among university students. For instance, Wade and Trathen (1989) studied the role of noting ideas in a text and its effects on recall. Of interest is the fact that they found that asking students to describe their strategies while studying reduced the amount of information students took notes on and had negative effects on recall. They concluded that verbal reporting during reading affects both the process and product of studying.

Magliano et al. (1999) conducted an experiment on how strategic processing during comprehension is affected by properties of the text and how different strategies (i.e., reading to explain, to associate, to predict, or simply to understand) can affect text retention. They compared silent and think-aloud conditions and found that a strategy to explain led to an increase in memory compared with a strategy to understand when reading was done silently but not when participants thought aloud. The authors argued that it is possible that thinking aloud eliminated the general benefits of reading to explain. Moreover, they pointed out that the process of describing the thoughts that occurred in a sentence may have strengthened memory representations for the explicit text. Indeed, story recall was better when participants thought aloud than when they read silently. In short, thinking aloud may improve memory for text because it requires a more conscious processing of text, though it eliminates the benefits of the student being induced to use an explanatory strategy (Magliano et al., 1999).

Following these results, we were interested in assessing the degree to which thinking aloud may become a source of cognitive overload (Sweller, 1994) in complex learning situations, which might distort processing or provide convergent evidence of the integration processes in conjunction with behavioral on-line measures. It might be that thinking aloud, as hypothesized by Ericsson and Simon (1980, 1993), does not interfere with learning from a task and perhaps creates only a slight increase in experimental time because of the need to think aloud and perform the task simultaneously. However, thinking aloud in conjunction with reading multiple texts and solving different tasks may overload a student's cognitive resources, resulting in decreased performance and/or learning. In terms of processing patterns, thinking aloud may affect the reading of texts, inducing greater concentration on explicit textual information, which might decrease the use of deep processing strategies such as in Magliano et al.'s (1999) study.

## Method

### Participants

Fifty-six undergraduate students with a mean age of 20 years who were enrolled in a psychology program at the University of Valencia, Valencia, Spain, participated in the experiment for course credit. Some participants were excluded because of problems with the on-line registration process. They were distributed into four conditions following a matching procedure based on their previous background knowledge level (see *Procedure* section). Half of the participants were assigned to the intertext task, whereas the other half answered intratext questions. Within each group, approximately half of the participants thought aloud while doing the task (i.e.,  $n_s = 11$  and 12 for the intertext and intratext questions, respectively), whereas the rest did the task under silent conditions (i.e.,  $n_s = 14$  and 13 for the intertext and intratext questions, respectively).

### Materials

*Documents and tasks.* Three texts from trustworthy Web sites (e.g., the National Institutes of Health) were selected according to length, comprehensibility, and content-relevance criteria. Thus, we guaranteed that texts both were written by a specialist and came from reliable sources. The texts presented information to be understood by a nonacademic in biology. Nonetheless, the content was not suitable for the general public, but rather for university-level students used to handling scientific texts and with general background knowledge in biology acquired previously.

Our main interest was to create a situation of learning from multiple texts based on complementary relationships across sources. This situation implies that, in order for a reader to wholly understand the specific issue (i.e., mechanisms by which bacteria become resistant and how resistance can be transmitted to other bacteria), he or she would need to process carefully the relevant pieces of information coming from each of the three texts and combine them. In other words, none of the sources gave the whole perspective on the issue; instead, the reader needed to select relevant units of information across sources and integrate them into a higher order representation going beyond the individual texts. The three texts (i.e., *Anti-Bacteria Resistance*, *New Perspectives on Bacteria Resistance*, and *Genetics of Bacteria Resistance*) were 684, 658, and 390 words long, respectively.

After conducting a detailed content analysis of the three texts to clearly specify which units of information were relevant to the specific issue, we selected 22 units as relevant (see Table 1). We (Raquel Cerdán and Eduardo Vidal-Abarca) performed content analysis and selected units, reaching an interrater agreement of more than 90%. The 22 idea units were grouped into four main content areas. These areas corresponded to the main subtopics included in the specific issue put to students, that is, description of bacteria, biological resistance mechanism, the transfer of bacteria resistance from some bacteria to others, and resistance responses. The units were differentially present in the three documents (see Table 1). Therefore, any student wishing to construct an integrated mental model would have needed to inspect all sources, select the relevant units of information, and integrate them. Though many units were located in different documents, five units repeated in two different texts (i.e., Ideas 7–9, 15, and 16; see Table 1). This

Table 1  
*Distribution of Contents Across Texts*

Idea	Content	Text	Paragraph
Area 1. Description of bacteria			
1	Bacteria are single-celled organisms with a reduced number of genes.	R	2-1
2	They multiply quickly.	R	2-1
3	They are highly capable of adapting to any kind of environment.	R	2-1
4	This is a key factor for the development of resistance to antibiotics.	R	2-1
Area 2. Biological resistance mechanisms			
5	When antibiotics appeared, many bacteria developed resistance mechanisms.	P	1-3
6	There are two resistance mechanisms.	P	1-3
7	Genetic mutation.	P, G	P 1-3, G 2-1
8	The transfer of resistance genes from one bacterium to other bacteria (plasmids)	P, G	P 1-3, G 2-1
9	Genetic mutation implies changes in the genetic information of bacteria.	P, G	P 1-3, G 2-1
10	These changes prevent them from responding to antibiotics.	P	1-3
11	Plasmids are pieces of extra-chromosomal DNA.	P	1-3
12	Plasmids produce mechanisms resistant to antibiotics.	P	1-3
13	Plasmids may produce resistance to more than one antibiotic. This is called multiresistance.	G	2-1
Area 3. The impact and transfer of resistance			
14	Even one random mutation can have a large impact due to bacteria's quick multiplication rate.	R	2-1
15	Resistance can be transmitted to other generations of the same bacteria.	P, R	P 1-3, R 2-1
16	Resistance can also be transmitted to other generations of bacteria not related to the original ones.	P, R	P 1-3, R 2-1
Area 4. Resistance responses			
17	Bacteria respond in three different ways to the lethal effects of antibiotics.	G	1-3
18	They can modify the antibiotic's chemistry.	G	1-3
19	They can degrade the antibiotic.	G	1-3
20	They can modify the target of the antibiotic in the bacteria.	G	1-3
21	They can stop antibiotics from penetrating.	G	1-3
22	They can expel the antibiotic.	G	1-3

*Note.* Area refers to the main content across texts. Paragraph refers to Read&Answer text divisions. R = *Anti-Bacteria Resistance*; P = *New Perspectives on Bacteria Resistance*; G = *Genetics of Bacteria Resistance*.

repetition of information units was not verbatim but at the level of meaning.

The four main content areas were the basis of the design of the two sorts of tasks. Writing the essay on the intertext question required the students to take into account the 22 units of information (see Table 1) and discard irrelevant ideas. Complementarily, four intratext questions that directly matched the four areas in the table of contents were formulated (see the Appendix for the two types of questions). Therefore, answering the intertext question promoted greater integration of the units as it required students to connect information from the three documents, although this task might have been more demanding than the other question. However, less integration was needed to answer the four intratext questions, as their answers were found only in one document, thus not requiring students to make intertext connections.

*Read&Answer software* (Vidal-Abarca & Martínez, 2002). Texts and tasks were presented on a computer screen using the software Read&Answer. The software presents readers with a full screen of text. All text except the segment currently selected by the reader is masked. Readers unmask a segment by clicking on it; when they unmask another segment, the first segment is remasked. Thus, only one segment is visible at a time. Readers can reread the segments in any order they choose (see Figure 1A). A segment can

be a word, sentence, or paragraph, depending on the unit the researcher establishes. In this study, a text segment was operationalized as a paragraph, which, as described below, was the level of text at which measures were taken in the Read&Answer system. Each text was presented in a maximum of two pages. The first and the second texts contained seven paragraphs each, and the last text contained only five. Each paragraph had a mean number of words of 90. Relevant units of information were located in four Read&Answer paragraphs, whereas the rest of the paragraphs were irrelevant to the questions in the tasks (see Table 1).

Read&Answer also presents the reader with a question screen divided into two parts, the upper part for the question and the lower part for the answer. This question screen can be accessed through a button on the navigation toolbar from any text that the student may be reading at a given moment, thus allowing flexibility in the question-answering process. The user clicks on each part of the question screen to either read the question or write in the answer box. A simple interface allows the reader to move from one question to another and from the question screen to the text screen, and vice versa (see Figure 1B).

Read&Answer automatically generates three outputs. The first is a list of all segments active at any given moment, which is sequentially ordered to follow the student's performance in the

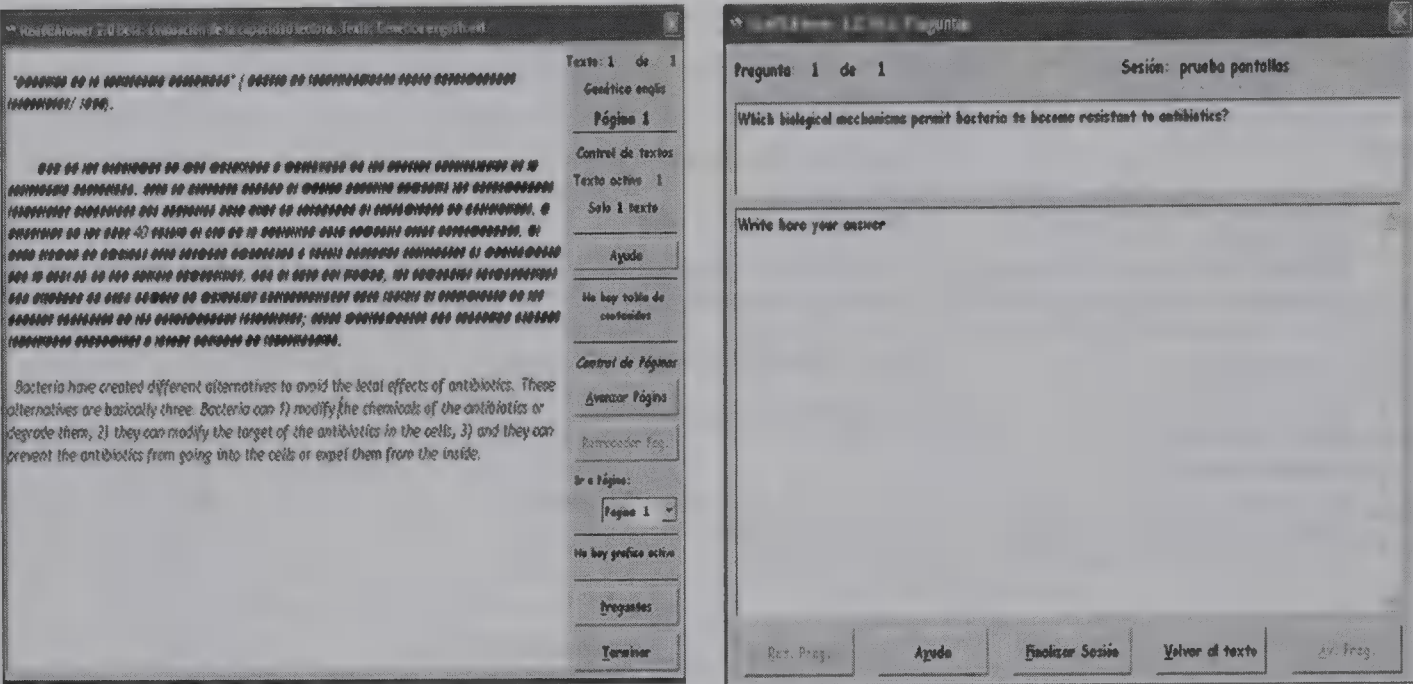

Figure 1. Read&Answer text (A) and question (B) screens.

experimental session. The software also records the length of time each segment is active. A text paragraph, a specific question, and the answer to every question are all segments. Thus, every action the reader undertakes, whether reading a text paragraph, reading a question, rereading a paragraph, or writing an answer, is recorded and included in the sequential list. The second output is a summary of the reader's behavior when he or she reads the text and answers the questions, including computed data such as the reading rate per word for the textual paragraphs, which the system calculates by dividing the total time to read that paragraph by the total number of words in that paragraph. The third output is the record of the reader's answers to each question. These three outputs allowed us to track students' strategic behavior when reading multiple sources on-line.

*Processing measures.* To measure students' processing of information, we took a number of on-line measures using the Read&Answer tracking system, assuming that they would contribute to explaining the product results. We first measured time on task. Time on task in seconds indicated how much time students needed to perform the reading and question-answering task. We also captured the students' processing of both relevant and non-relevant units of information by measuring the mean time per word that students in the different conditions spent reading the two sorts of units of information.

Finally, we measured integration of information by counting nonconsecutive readings of relevant units of information, which indicated an effort to connect and integrate the two paragraphs. We also measured the single-unit pattern of processing by counting the number of times a student, after reading a paragraph with relevant information, performed another action (e.g., reading a question, writing an answer, or going to a paragraph with nonrelevant information) and then returned to the paragraph with the previously read relevant information. This behavior indicated the processing of text paragraphs in isolation from other paragraphs in the three texts.

Students' think-aloud protocols were also analyzed to obtain complementary evidence for processing. Students' verbalizations were transcribed and divided into idea units, that is, sentences with a subject and a verb. Each idea unit was coded according to the following categories: (a) *task*: verbalizations associated with the process of performing the task or the use of the software (e.g., "These are the instructions, aren't they? I read them aloud. Okay, I will start by reading the questions."); (b) *search*: verbalizations regarding searching and locating information in the texts, regardless of whether it was relevant or irrelevant (e.g., "Okay, I think this was located in Text 3. I will reread Text 3 to find the answer."); (c) *relevant-unit understanding*: verbalizations about relevant units of information that indicated deep comprehension, including inferences, summaries, elaborations, and explanations (e.g., a student said the following when she was trying to understand the mechanisms by which bacteria produce resistance to antibiotics: "Here they more or less give a different point of view of how resistance is produced; given that they are mono-cells and with a tiny amount of genes, by mutation of these genes, they can create resistance, which is transmitted to their descendants"); (d) *non-relevant-unit understanding*: deep comprehension verbalizations, but referring to irrelevant units of information; (e) *superficial understanding*: verbalizations indicating paraphrases and irrelevant associations, no matter if they referred to relevant or irrelevant units of information; (f) *writing self-regulation*: verbalizations reflecting self-regulation of the answering process (e.g., "I go to Question 3, because I don't know what to answer in this one"; "I think this one is correct this way"); (g) *superficial writing*: verbalizations indicating mainly how students manage orthography in the writing process (e.g., "I am not sure if I should add a period at the end of this sentence"). Verbal protocols were coded by two experimenters according to these categories. Coding was done following the procedure explained previously: cooperative scoring for training, coding approximately one third of protocols

separately, but checking interrater agreement until reaching 95% agreement; then Raquel Cerdán coded the rest of the protocols.

*Control measures.* We used three control measures to make sure the experimental groups did not differ in measures that could contaminate subsequent results. The first control measure was prior background knowledge. As students were expected to learn selected content on bacteria resistance to antibiotics from three different texts, and differences in previous background knowledge may have interfered with our results, we created a measure to control for this possible effect. In general, we expected students to have similar levels of basic knowledge of general biological mechanisms from earlier instruction in school. Additionally, we expected them not to be specialists in bacteria resistance mechanisms. This way, they would be a suitable sample for learning this specific knowledge in our experiment.

To ascertain students' level of knowledge of biology, we administered a background knowledge test that consisted of 15 true/false items on the general domain of biology relevant for the texts, although 3 of the 15 items directly assessed specific content on bacteria resistance that students would encounter in the texts. Of these items, 8 were true and 7 false, and the test was scored up to 15 points. An example of a false general domain item was the following: "Bacteria are multi-celled organisms." This contrasted with an example of a true topic-specific item: "Bacteria resistance is favored by the misuse of antibiotics both in humans and animals." Reliability analyses were conducted with an independent sample of 45 psychology students. Cronbach's alpha was significant, with a value of .97.

The second control measure was lexical access. A Spanish test consisting of a list of 40 words and a complementary list of 40 pseudowords was presented to the students, and we registered the time students took and the mistakes they made in reading aloud both lists (Ramos & Cuetos, 2000). Third, we controlled for keyboarding skills, as students used a computer to answer the questions. Participants were given 2 min to type a 146-word text into the computer. Then we counted the number of words they were able to type.

*Tests and scoring.* To assess the effectiveness of the two tasks at different levels of learning, we designed three measures: (a) performance on the tasks, (b) a sentence verification task, and (c) a transfer task. The first captured how well students did on either the intertext task or the four intratext questions, whereas the other measures were applied after the students finished the tasks. One measured superficial understanding, whereas the other measured deep learning.

To measure performance on the tasks, we counted whether the 22 target ideas that students were expected to include in their answers were present, as these target ideas were shared in both conditions. Thus, a student performing the intertext task perfectly would obtain 22 points, 1 for each idea included in the answer. Performance scores were transformed into percentages to facilitate interpretation. The scoring procedure was conducted by two experimenters. To guarantee equality in criteria, at least two question sets were scored cooperatively and compared between scorers. Discrepancies would be discussed and resolved. Then, new question sets were scored separately and rater agreement was checked after scoring each protocol until raters agreed on at least 95% of decisions (this was reached after scoring approximately one third

of the protocols). The rest of the protocols were scored by Raquel Cerdán alone.

The sentence verification test consisted of 18 items that directly matched the relevant units of information that students should have gone through in the experimental session. Each of the items included either one or two of the units present in the basic table of contents across texts. Examples of items are the following: "Plasmids are DNA pieces" (false) and "Plasmids produce resistance mechanisms against antibiotics" (true). These items correspond to Ideas 11 and 12 in the table of contents, respectively. Reliability analyses were again conducted with an independent sample of 45 psychology students. Cronbach's alpha was significant, with a value of .94.

The transfer test consisted of a practical case in which students had to apply to a new situation their new knowledge on bacteria resistance to antibiotics. Because of the need to transfer coherent knowledge acquired from reading and to connect the relevant paragraphs of information, we assumed the transfer test would measure integrated knowledge. Thus, students were presented with the following practical situation: "Imagine you have a sore throat and you go to the doctor for treatment. The doctor informs you that the cause of your illness is a bacterial infection. You should take antibiotics for an entire week. You start your treatment, following the doctor's advice, but after 3 days you feel perfectly well and decide to stop taking antibiotics." Based on this situation, students were required to answer the following questions: (a) "Do you think the antibiotic has been successful in destroying all the bacteria responsible for your illness, and why?"; (b) "What explanation can you give?"; (c) "What further implications would occur because you stopped taking the antibiotics?" The test was scored up to 9 points, and a percentage of success was obtained for each student.

The criteria to score the three questions were the following. For the first question students were expected to answer no (1 point). They should reason that when antibiotics are used improperly, bacteria resistance may appear (1 point), and hence these antibiotics would be unable to destroy all of the bacteria responsible for the illness (1 point). For the second question students should have given a biological explanation for the reasons given for the first question: Bacteria may have become resistant to antibiotics (1 point), either because genetic mutation had taken place (1 point) or because DNA pieces producing bacteria resistance had been created (1 point). Finally, a complete answer to the third question included the following causal chain: Bacterial resistance can easily be transmitted to other bacteria (1 point). This transmission is favored by the bacteria's high multiplication rate (1 point). Thus, an individual action (e.g., to stop taking antibiotics) may affect the long-term effectiveness of a specific antibiotic (1 point). The scoring system was the same as that explained previously, involving a collaborative training phase, then an independent scoring phase in which interrater agreement was checked until reaching 95% agreement (which was also achieved after scoring approximately 25% of the protocols). At that point the rest of the protocols were scored by Raquel Cerdán.

### *Procedure*

Students were assessed individually during two sessions on 2 different days. In the first session, students were tested on the three control measures (i.e., previous background knowledge, lexical

access, and keyboarding skill). Students were matched to one of the four experimental conditions (Think Aloud  $\times$  Task), taking into account their scores on the previous background knowledge test so that the mean score of students in the four conditions would be equivalent. Correction of the previous background knowledge test and assignment to each of the conditions was done while a specially trained assistant tested the students on the lexical access and keyboarding tasks in order to match the students to the four experimental conditions. Afterward, students were trained to use the Read&Answer software with a task similar to the one they had to do in the second session. Specifically, students were first told to read the task, either the intertext essay or the four intratext questions, and then move about freely in the software, reading the texts as they wished and going back to their task whenever they wanted.

In Session Two, students did the experimental task. They first read either the intertext task or the four intratext questions, and the titles of the documents. Thus, they knew the sort of question they had to answer in advance. Then students were free to read and answer their respective questions at will, being free to read and reread the documents when doing their task. After finishing, they were tested first on the sentence verification test and then on the transfer test. These two final tests were performed with paper and pencil and without a time limit, though students used a similar amount of time for the two tasks (approximately half an hour).

The procedure was slightly different for the students in the two think-aloud groups. In the first session the training also emphasized that students should read aloud the textual paragraphs and simultaneously say whatever came to their minds during this performance. Students were invited to sit in front of the computer and were given a headphone with a microphone to record their verbalizations. We told them to say aloud whatever crossed their minds while reading the texts and answering the questions, but without making an extra effort to verbalize, as they should say aloud only naturally appearing thoughts that occurred while performing the task. We indicated to students that they were expected to verbalize (a) after reading each of the text paragraphs of the documents; (b) while moving through the software (i.e., changing from one document to another and going from the text screen to the question-answering screen); and (c) before, during, or after reading the questions and writing the answers. Then one of the authors modeled the think-aloud procedure for 5 min using different types of verbalizations, such as those implying repetition, paraphrases, or inferences.

Results

A number of  $2 \times 2$  analyses of variance (ANOVAs), with the two main variables task (intertext task vs. intratext questions) and think aloud (yes vs. no), were conducted for most of the dependent measures. We first briefly present results for the control measures. Then we explain the product measures and those capturing the processing. After that, correlations between product and processing measures are presented.

Control Measurements

We found no significant differences for any of the control measurements: previous background knowledge, lexical access skill, or, finally, keyboarding skill (see Table 2). Therefore, we had strong assurance that the experimental conditions did not differ in measures that could have interfered in subsequent analyses. Of interest is the fact that the mean score in all groups for background knowledge was 9.5, out of a maximum of 15 points. This finding indicates that participants had a relatively high level of general domain knowledge that would have allowed the learning of more specific issues, such as bacteria resistance.

Product Measurements

*Performance.* Neither the type of task nor the think-aloud conditions generated significant main effects on performance,  $F(1, 46) = 0.10, p = .79$ ; and  $F(1, 46) = 1.13, p = .48$ , for task and think-aloud, respectively, though the interaction between them was marginally significant,  $F(1, 46) = 3.12, p = .08, \eta^2 = .06$ . Thus, as can be seen in Table 3, on intratext questions participants scored higher when they thought aloud than when they did not, whereas thinking aloud did not make any difference for the intertext task. This interaction effect could be interpreted as a *textual-focusing effect* of thinking aloud, which is added to the local processing effects of intratext questions. Thinking aloud could have strengthened the student's maintenance of textual information in short-term memory to a greater extent than the non-think-aloud condition in a situation in which local processing was enhanced by answering intratext questions. It could have made students who thought aloud and answered intratext questions increase their performance scores.

*Sentence verification test.* Neither the type of task effect nor the think-aloud conditions produced significant results on sentence

Intertext	47.52	25.98	51.01	30.10	40.90	16.34
Intratext	63.25	25.45	51.85	26.52	33.79	12.63
Non-think-aloud						
Intertext	46.75	22.58	53.57	22.70	53.96	15.47
Intratext	38.81	20.54	41.02	23.62	40.59	11.19

Note. Data are in percentages.

verification,  $F(1, 46) = 0.64$ ,  $p = .42$ ,  $\eta^2 = .14$ ;  $F(1, 46) = 0.32$ ,  $p = .57$ ,  $\eta^2 = .00$ ; and  $F(1, 46) = 0.84$ ,  $p = .36$ ,  $\eta^2 = .01$ , for task, think-aloud, and the interaction effects, respectively (see Table 3). Thus, as predicted, the two sorts of tasks were equally effective for identifying and understanding the basic ideas that students should have considered to do their task.

*Transfer test.* The two main variables produced significant effects (see Table 3). Thus, participants performing the intertext task scored higher ( $M = 48.22$ ,  $SD = 16.87$ ) than participants answering intratext questions ( $M = 37.33$ ,  $SD = 12.16$ ),  $F(1, 46) = 6.21$ ,  $p < .05$ ,  $\eta^2 = .12$ , which was predicted in our first hypothesis. Additionally, participants who did not think aloud scored higher ( $M = 47.53$ ,  $SD = 14.96$ ) than those who thought aloud ( $M = 37.19$ ,  $SD = 14.96$ ),  $F(1, 46) = 6.61$ ,  $p < .05$ ,  $\eta^2 = .11$ .

Therefore, two main results are apparent. First, answering the intertext questions, that is, writing a global essay, produces deeper learning than answering intratext questions, though no differences appear at the level of superficial comprehension, that is, performance on the tasks and the sentence verification task. These results were in agreement with our predictions and should have been related to the processing measures that we are explaining. Second, thinking aloud seems to hinder deep learning from multiple documents when the task is to select and integrate a subset of information across the documents, but it also seems to strengthen the local processing of answering intratext questions. Processing measures should contribute to explaining these results.

### Processing Measures

*Time on task.* To obtain the first on-line evidence of the task effects, we globally counted the number of seconds students spent performing the reading and answering tasks. This measure was an indicator of how resource demanding the task was and how thinking aloud may have affected the experimental process. Thus, we conducted a  $2 \times 2$  ANOVA with independent variables task (intertext task vs. intratext questions) and think aloud (yes vs. no).

The type of task did not produce significant effects ( $M = 2,291.48$  s,  $SD = 886.05$ ; and  $M = 2,615.28$  s,  $SD = 898.19$ , for the intertext task and intratext questions, respectively). However, thinking aloud did produce differences, as students who thought aloud spent more time on the whole experiment ( $M = 2,906.64$  s,  $SD = 856.39$ ) than those who did not ( $M = 2,067.27$  s,  $SD = 750.11$ ),  $F(1, 46) = 14.19$ ,  $p < .05$ ,  $\eta^2 = .23$ . The interaction between the two variables was also significant. Participants answering intratext questions needed more time for the experiment ( $M = 3,271.81$  s,  $SD = 655.09$ ) than those answering the intertext task, but only for the think-aloud condition,  $F(1, 46) = 3.99$ ,  $p < .05$ ,  $\eta^2 = .08$  (see Table 4). Thus, on the whole, thinking aloud increased the time needed to perform the tasks in comparison with participants performing silently, and the effect was stronger for the intratext questions task. Therefore, processing data support the textual focusing effect we mentioned when performance results were analyzed. Apparently, thinking aloud strengthened the students' maintenance of text information in short-term memory, enhancing the local processing caused by answering intratext questions, which provoked the high performance of students in this condition.

*Processing relevant vs. nonrelevant units of information.* The benefits of the intertext task found in the transfer test should have been apparent on the processing of the relevant information when doing the tasks. To examine this issue we analyzed the time per word of the students' processing when reading the text paragraphs with the 22 relevant units of information and when reading the rest of information, that is, the nonrelevant information. A  $2 \times 2 \times 2$  ANOVA was conducted with task and think aloud as between-subjects variables and type of information (relevant vs. irrelevant) as a within-subjects variable. The task variable produced significant differences, as intertext task participants read textual information more slowly, that is, at a higher time per word rate ( $M = 0.19$ ,  $SD = 0.06$ ), than students answering intratext questions ( $M = 0.15$ ,  $SD = 0.05$ ),  $F(1, 46) = 4.99$ ,  $p < .05$ ,  $\eta^2 = .09$ . This

Table 4  
Means and Standard Deviations of the Five Processing Measurements

Group and task	Time on task		Time per word relevant		Time per word nonrelevant		Integration		Single-unit processing	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Think aloud										
Intertext	2,508.27	898.24	0:20	0.07	0.22	0.05	4.55	2.018	12.00	10.45
Intratext	3,271.81	655.09	0.18	0.05	0.20	0.09	1.83	0.937	26.50	12.602
Non-think-aloud										
Intertext	2,121.14	870.47	0.21	0.09	0.13	0.05	6.71	5.622	10.07	6.765
Intratext	2,009.25	625.48	0.11	0.03	0.12	0.04	1.00	0.91	26.69	6.921

finding means that the intertext task induced a more detailed processing of documents than the intratext question task. The think-aloud variable also produced significant differences. Hence, think-aloud participants read globally more slowly ( $M = 0.20$ ,  $SD = 0.06$ ) than non-think-aloud students ( $M = 0.14$ ,  $SD = 0.05$ ),  $F(1, 46) = 12.09$ ,  $p < .05$ ,  $\eta^2 = .20$ , which seems logical as the time devoted to thinking aloud was counted as time for processing.

Three interesting interaction effects were apparent. First, the interaction between task and type of information was significant,  $F(1, 46) = 4.98$ ,  $p < .05$ ,  $\eta^2 = .09$  (see Figure 2). Thus, whereas intertext task participants read relevant information more slowly than irrelevant information, intratext question students read both sorts of information at a similar rate of speed. This may explain why answering an intertext task was more beneficial for deep learning than was answering intratext questions. Second, the interaction between thinking aloud and type of information was also significant,  $F(1, 46) = 7.43$ ,  $p < .05$ ,  $\eta^2 = .13$ . Relevant and nonrelevant information was read at a similar speed in the think-aloud condition ( $M = 0.19$ ,  $SD = 0.06$ ;  $M = 0.21$ ,  $SD = 0.07$ , for relevant and irrelevant information, respectively), whereas in the non-think-aloud condition, relevant information was read more slowly than nonrelevant information ( $M = 0.16$ ,  $SD = 0.06$ ;  $M = 0.12$ ,  $SD = 0.04$ , for relevant and irrelevant information, respectively). It seems that thinking aloud induced students to process all types of information at the same level, regardless of its relevance, which may explain why thinking aloud also hindered the transfer test scores.

Finally, a triple interaction among task, thinking aloud, and type of information was found,  $F(1, 46) = 5.79$ ,  $p < .05$ ,  $\eta^2 = .11$  (see Table 4). If we consider the relevant information, when students did not think aloud, those who performed the intertext task read more slowly than students who answered intratext questions, whereas no differences between the two sorts of tasks were found when students did the think-aloud task. However, when irrelevant information is considered, no differences were apparent between the two sorts of tasks, either when students thought aloud or when they did not, and students who did not think aloud read this irrelevant information more quickly than those who did think aloud. This finding indicates that the benefit of performing the intertext task over the intratext questions concentrates on the students' processing of the relevant information when they did not

think aloud. Therefore, the negative impact of thinking aloud on processing was confirmed.

*Integration versus single-unit processing of relevant units of information.* Integration of information should be apparent when a student reading a text paragraph with relevant information jumps to a nonconsecutive paragraph that also contains relevant units of information, no matter if in between the reader rereads a question paragraph or makes a quick visit to an irrelevant paragraph in the search process. One can assume that the reader is making an effort to connect and integrate the two paragraphs with relevant information. For this connection between two relevant paragraphs to occur, the in-between reading times (i.e., reading other irrelevant paragraphs or reading the question) should be less than the reading time of the two paragraphs being connected. Hence, one can assume a connection between two relevant paragraphs is taking place when two criteria are met: (a) the reading of the two relevant paragraphs is consecutive, and (b) the reading times of the in-between information are less than the reading times of the two relevant paragraphs being connected.

A completely different behavior occurs when a student reading a paragraph with relevant information performs another action, such as reading a question, writing an answer, or going to a paragraph with irrelevant information, and then goes back to the paragraph with relevant information previously read for further slow processing. This behavior reflects the processing of a specific unit of information without integration with other units. It should be noted that many students returned to the same unit repeatedly, but we counted these visits as one instance of processing, as they referred to the same unit.

We call the first instance *integration processing*, as it indicated an effort to connect different relevant paragraphs of the text, and the second *single-unit processing*, as it reflected the processing of the textual paragraphs in isolation to the other paragraphs. We counted the number of times a student either integrated information or showed the single-unit processing strategy just mentioned by applying the criteria just explained.

Two  $2 \times 2$  ANOVAs were conducted with task and think aloud as independent variables, and integration and single-unit processing as dependent variables. Only the task variable yielded significant results for both dependent measures (see Table 4). Students in the intertext question task, as expected, integrated information to a greater extent ( $M = 5.76$ ,  $SD = 4.47$ ) than did intratext question students ( $M = 1.40$ ,  $SD = 1.00$ ),  $F(1, 46) = 21.48$ ,  $p < .05$ ,  $\eta^2 = .31$ . The opposite trend was found for the single-unit processing measure, as intratext question students showed more single-unit processing ( $M = 26.60$ ,  $SD = 9.83$ ) than did intertext question participants ( $M = 10.92$ ,  $SD = 8.44$ ),  $F(1, 46) = 34.45$ ,  $p < .05$ ,  $\eta^2 = .42$ . The first result contributes to explaining why performing the intertext task produced higher scores on the transfer test than did answering intratext questions, as jumping from one relevant information paragraph to another contributes to the integration of the two paragraphs and consequently to deep understanding. However, the repeated processing of one paragraph does not contribute to integration but indicates the processing of one isolated unit of information.

*Analysis of think-aloud protocols.* For each student we obtained a cumulative score in each of the seven think-aloud categories mentioned in the *Method* section (i.e., task, search,

Figure 2. Interaction effect between task and type of information. Mean relevant and nonrelevant time per word rates for intertext and intratext questions.

Table 5  
*Think-Aloud Categories*

Task	Task		Search		Relevant-unit understanding		Nonrelevant-unit understanding		Superficial text processing		Writing self-regulation		Superficial writing	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Intertext	93.36	37.77	25.81	29.12	15.18	12.57	9.72	10.55	15.72	6.00	55.18	25.63	2.72	2.96
Intrertext	109.91	33.45	28.41	13.02	6.25	6.67	14.50	26.35	24.91	37.21	52.41	23.93	8.75	6.21

Note. Data are frequencies.

relevant-unit and nonrelevant-unit understanding, superficial understanding, writing self-regulation, and superficial writing) based on the number of times each category appeared in a verbal protocol (see Table 5). With these categories as dependent variables, we conducted one-way ANOVAs, with task (intertext task vs. intratext questions) as the independent variable. Only two analyses yielded significant results. First, students performing the intertext task ( $M = 15.18$ ,  $SD = 12.57$ ) verbalized significantly more on understanding relevant information than those who answered intratext questions ( $M = 6.25$ ,  $SD = 6.67$ ),  $F(1, 21) = 4.64$ ,  $p < .05$ ,  $\eta^2 = .21$ . Second, students answering the intertext task produced fewer superficial writing comments ( $M = 2.72$ ,  $SD = 2.96$ ) than students answering intratext questions ( $M = 8.75$ ,  $SD = 6.21$ ),  $F(1, 21) = 8.53$ ,  $p < .05$ ,  $\eta^2 = .46$ . These two results provide convergent evidence for our claim that the intertext task promoted a deeper processing of the multiple sources in comparison to the intratext questions.

### *Correlations Between Product and Processing Measurements*

To gather additional evidence to support the relationship between students' processing and the results obtained in the three product measures, we obtained the correlation between the processing and product measures (see Table 6). Performance on task was positively related to single-unit processing ( $r = .356$ ,  $p < .05$ ) and negatively related to time per word reading relevant units of information ( $r = -.332$ ,  $p < .05$ ). The opposite relationship was seen for scores on the sentence verification test, which were negatively related to single-unit pro-

cessing scores ( $r = -.352$ ,  $p < .05$ ) and positively related to time per word reading relevant units of information ( $r = .348$ ,  $p < .05$ ). Transfer test scores were also negatively related to single-unit processing ( $r = -.300$ ,  $p < .05$ ) but strongly related to integration behavior ( $r = .454$ ,  $p < .01$ ).

We submitted the processing variables to three stepwise multiple regression analyses to determine the best model for predicting the three product measurements. As can be seen in Table 7, only single-unit processing accounted for almost 11% of the variance in the performance scores, and no other processing measure accounted for a significant amount of variance above that mentioned. Single-unit processing was also the best and single predictor of variance (10.6%) in the sentence verification scores, though the beta coefficient was negative. In terms of the transfer test, the scores on integration behavior accounted for 19% of the variance, and no other processing measure made a significant contribution. Thus, the two variables related to the process of integration (i.e., single-unit processing and integration behaviors) were the best predictors of the three product measures, though their role was very different depending on the specific product measure we considered. Single-unit processing seemed to indicate very superficial processing characterized by searching for, locating, and memorizing information. This behavior was sufficient to succeed in performing the tasks during training but was negatively related to truly understanding the ideas found in the documents. Integration predicted transfer scores, the deepest comprehension measurement. It should also be noted that performance on the task was not related to the other two measures (i.e., sentence verification and transfer tests), whereas these two measures were closely interrelated ( $r = .357$ ,  $p < .05$ ).

Table 6

## Discussion

Our main objectives for the present experiment were (a) to deepen our understanding of the mental processes involved in integrating information from multiple documents and to find behavioral correlates for these processes; and (b) to test the effectiveness of two sorts of tasks to induce integration and deep learning from multiple documents, that is, either writing an intertext essay or answering intratext questions, both drawing on the same text information. Accordingly, we hypothesized that students writing the essay or intertext question would outperform students answering the intratext questions on deep learning measures, but not on superficial comprehension, and that this differential effect could be explained from on-line processing measures while doing the tasks. Additionally, we wanted to explore possible interference effects of thinking aloud while doing the tasks, given the debate about this.

Writing an intertext essay, which according to our design should have made students integrate the target relevant paragraphs across the three texts, was indeed the most effective task for fostering deep learning, as evidenced in the transfer test. Thus, students who wrote the essay were better able to apply their new knowledge on bacteria resistance to antibiotics to a new situation than were those who answered intratext questions. However, when considering performance scores on the tasks or results at the level of identifying and understanding isolated relevant ideas, there were no differences between writing an intertext essay and answering intratext questions. Thus, measures of performance and superficial comprehension are not coincident with measures of deeper comprehension and learning (Schmidt & Bjork, 1992; Wiley & Voss, 1999).

Our analysis of students' processes based on behavioral data allows us to explain these results. The instruction to write an essay on an intertext question made students read the relevant information more slowly than irrelevant information, whereas no differences between the processing of the two types of information were found when students answered the intratext questions. In addition, students who wrote the essay showed more integration behavior than those who answered intratext questions (such behavior defined as reading a text paragraph with relevant information, then jumping to another nonconsecutive paragraph that also contains relevant units of information, whether or not the reader performs other actions in between these tasks). However, single-unit processing behaviors were more frequent in answering intratext questions than in writing the essay on the intertext question. We defined these behaviors as reading a paragraph with relevant information, then doing other actions, and finally going back to the paragraph with the relevant information previously read for slow processing.

Therefore, writing an essay on a broad and global issue makes students concentrate on the information relevant to the essay topic

and integrate all of the information even though it may be a highly demanding task. Indeed, connecting different paragraphs of information coming from different sources seems to be more demanding for the student than inspecting a single text, as the slower reading rates in textual paragraphs indicate, though this hypothesis on the different cognitive load of each kind of task should be tested in more detail in future research. However, dividing a broad issue into smaller questions and asking students to answer these questions, which seems a less demanding task, makes students concentrate on processing all of the information independent of its relevance for the task and causes more single-unit processing, as the focus is on searching specific information to answer specific questions. These different patterns of processing are coincident with those found by other researchers (Cerdán et al., 2007; Rouet et al., 2001).

Thus, integrating information from multiple documents in order to form a coherent representation from a subset of information in the documents requires the reader to concentrate on that information and process it more carefully than the rest of the information, which is similar to the behavior of good learners reported by Goldman (2004). It also means that when the reader finds information connected to other information he or she goes from one to the other in order to integrate the two pieces of information. This behavior is similar to the reinstatement and integration behavior reported by Mannes and Hoyer (1996). These two behaviors, which characterized the intertext essay task, are in opposition to the single-unit processing behavior fostered by asking students to answer more narrow intratext questions covering the same information.

Correlational data support these conclusions and the distinction between performance and learning (Schmidt & Bjork, 1992), as well as that between memory and learning (Kintsch, 1998). Regarding the first distinction, simply performing the task of either answering intratext questions or writing an essay with information explicit in a number of documents while having them available can be achieved by processing isolated units of information at a very superficial level, that is, searching, finding, and copying explicit information. In fact, performance on both tasks correlates neither with understanding and recalling, as measured by the sentence verification test, nor with deep comprehension, as measured by the transfer test. However, deep learning, as measured by the transfer test, depends mainly on integrating information across documents. With regard to the distinction between memory and learning, our data show that whereas scores on the sentence verification test, which involves mainly memory, are not related to integrating information, scores on the transfer test, which measures learning (Kintsch, 1998), are significantly related to integration. Thus, we provide evidence for the distinctions mentioned already in a situation not previously investigated, that is, the integration of infor-

mation from multiple documents, and we do so by using new processing measures.

Regarding the use of the think-aloud procedure in multiple text design, data from verbal protocols provide convergent evidence for behavioral results showing that the intertext essay task promoted a deeper processing of the multiple sources (i.e., more verbalizations about relevant units of information, which indicates deep comprehension, and fewer superficial writing verbalizations) in comparison to intratext questions. Our study also shows that making students think aloud globally increases the time needed to read the texts and perform the experimental task, as well as apparently interferes with deep learning results. Thinking aloud also made students read in a more homogeneous pattern without discriminating between relevant and irrelevant information, in comparison to the silent condition. Finally, thinking aloud tended to increase performance and sentence-verification scores, especially for students answering intratext questions.

Hence, as predicted by Ericsson and Simon (1980, 1993) thinking aloud created an increase in experimental time and a decrease in reading speed, a consequence of making students perform two tasks simultaneously (reading and thinking aloud). However, thinking aloud tended to increase text-based scores and decrease deep learning. Other authors, as reviewed earlier, also found interference effects for the think-aloud methodology. Wade and Trathen (1989) demonstrated that thinking aloud was detrimental for a task requiring the noting of ideas. Magliano et al. (1999) found that thinking aloud limited the higher level effects of induced reading strategies but facilitated memory for text. It seems that, at least for college students, thinking aloud forces an explicit concentration on surface textual information and limits the possibility of deeper processing activities because of cognitive overload (Sweller, 1994; Sweller, Van Merriënboer, & Paas, 1998). It may be that thinking aloud is regarded as an important assessment component in the experiment, hence students become committed to the think-aloud instructions, understanding them as instructions to paraphrase as much as possible and omit other deeper processing activities when reading the texts.

In sum, in the present experiment we confirmed that selecting relevant units of information and combining them by going from one to another are important processes for achieving integration from multiple documents, whereas the processing of isolated units of information seriously interferes with integration. However, integration across documents is highly influenced by the task that students are asked to perform in order to integrate information. The more integration a task requires, the better the results in terms of the learning it produces, although no differences in terms of a more superficial level of understanding are observed. It should be noted that the type of integration we dealt with in this study—that is, reading to select, process, and integrate a subset of information from multiple documents to describe and explain a physical phenomenon—is an important and complex skill in the knowledge society. Nowadays students are expected not only to understand a single text, but also to be able to integrate information from multiple sources and to use it for different purposes. We have just analyzed the role of different tasks in achieving such integration for university students. Other issues such as the role of sources' reliability, individual and developmental differences, the impact of previous background knowledge, and teaching strategies to foster this sort of integration still need to be investigated.

# A Comparison of Three Measures of Cognitive Load: Evidence for Separable Measures of Intrinsic, Extraneous, and Germane Load

Krista E. DeLeeuw and Richard E. Mayer  
University of California, Santa Barbara

Understanding how to measure cognitive load is a fundamental challenge for cognitive load theory. In 2 experiments, 155 college students (ages = 17 to 22; 49 men and 106 women) with low domain knowledge learned from a multimedia lesson on electric motors. At 8 points during learning, their cognitive load was measured via self-report scales (mental effort ratings) and response time to a secondary visual monitoring task, and they completed a difficulty rating scale at the end of the lesson. Correlations among the three measures were generally low. Analyses of variance indicated that the response time measure was most sensitive to manipulations of extraneous processing (created by adding redundant text), effort ratings were most sensitive to manipulations of intrinsic processing (created by sentence complexity), and difficulty ratings were most sensitive to indications of germane processing (reflected by transfer test performance). Results are consistent with a triarchic theory of cognitive load in which different aspects of cognitive load may be tapped by different measures of cognitive load.

**Keywords:** cognitive load, measurement, education, multimedia, learning

Suppose a student viewed a narrated animation explaining how an electric motor works, such as that partially shown in the left panel of Figure 1. The lesson lasts about 6 min and explains how electricity flows from a battery and crosses a magnetic field, which in turn creates a force that moves a wire loop.

A major challenge in designing multimedia lessons such as the electric motor lesson is to be sensitive to the learner's cognitive load during learning. In particular, the lesson should be designed so that the amount of cognitive processing required for learning at any one time does not exceed the learner's processing capacity (Mayer, 2001, 2005a; Mayer & Moreno, 2003; Sweller, 1999, 2005). However, researchers have not yet reached consensus on how to measure cognitive load during learning or even whether the various cognitive load measures are tapping the same construct (Brünken, Plass, & Luetner, 2003; Paas, Tuovinen, Tabbers, & van Gerven, 2003).

According to a triarchic theory of cognitive load based on cognitive load theory (Sweller, 1999, 2005) and the cognitive theory of multimedia learning (Mayer, 2001, 2005a; Mayer & Moreno, 2003), there are three kinds of cognitive processing during learning that can contribute to cognitive load: (a) *extraneous processing*, in which the learner engages in cognitive processing that does not support the learning objective (and that is increased by poor layout such as having printed words on a page and their corresponding graphics on another page); (b) *intrinsic (or essential) processing*, in which the learner engages in cognitive processing that is essential for comprehending the material (and that depends on the complexity of material, namely the number of interacting elements that must be kept in mind at any one time);

and (c) *germane (or generative) processing*, in which the learner engages in deep cognitive processing such as mentally organizing the material and relating it to prior knowledge (and that depends on the learner's motivation and prior knowledge, as well as prompts and support in the lesson). Table 1 gives examples of how each of these three facets of cognitive load can be manipulated within our multimedia learning situation involving a narrated animation about how an electric motor works.

First, one way to manipulate extraneous processing in a multimedia lesson such as the electric motor lesson is through redundancy. A nonredundant lesson consists of presenting concurrent animation and narration, as summarized in the left panel of Figure 1; a redundant lesson consists of presenting concurrent animation, narration, and on-screen text, as summarized in the right panel of Figure 1. The on-screen text is redundant with the narration because both contain the same words and are presented at the same time. Redundancy can create extraneous cognitive load because the learner must expend precious cognitive capacity on reconciling the two verbal streams (i.e., checking to make sure the spoken words correspond to the printed words) and the learner must scan back and forth between the printed words and the animation (Mayer, 2005b). The processes of reconciling and scanning are forms of extraneous cognitive processing because they do not support the instructional objective (i.e., understanding how an electric motor works).

Second, one way to manipulate intrinsic processing in the electric motor lesson is through the complexity of the sentences. A low-complexity sentence (such as Sentence 1 in Figure 2) requires the learner to hold only a few concepts in working memory to understand the essential point, whereas a high-complexity sentence (such as Sentence 7 in Figure 2) requires the learner to hold many concepts in working memory to understand the essential point. Therefore, measures of cognitive load should reveal lower load after a low-complexity sentence than after a high-complexity sen-

Non-Redundant

Redundant

Narration: “When the motor is switched on, electrons flow from the negative terminal of the battery through the yellow wire to the end of the yellow wire. Electrons flow from the end of the yellow wire through the commutator, then through the red half of the commutator, then through the wire loop to the red half of the commutator...”

Figure 1. Frames from nonredundant and redundant lessons on how an electric motor works.

Table 1  
*Three Ways of Creating Cognitive Load in Multimedia Learning*

Type of cognitive load	Example of cognitive load manipulation
Extraneous load	Redundancy: Redundant presentation has concurrent animation, narration, and on-screen text; nonredundant presentation has concurrent animation and narration.
Intrinsic load	Complexity: A high-complexity sentence involves many interacting concepts; a low-complexity sentence involves few interacting concepts.
Germane load	Transfer: Low-transfer students are less likely to have engaged in germane processing during learning; high-transfer students are more likely to have engaged in germane processing during learning.

tence. Sentence complexity can create intrinsic cognitive processing because the learner needs to coordinate more pieces of information essential to comprehension (Mayer, 2005a; Sweller, 1999).

Third, one way to examine differences in germane processing in the electric motor lesson is to compare students who score

high on a subsequent test of problem-solving transfer with those who score low. High-transfer learners are more likely to have engaged in higher amounts of germane processing during learning than are low-transfer learners (Mayer, 2001, 2005a). Figure 3 shows a transfer test question along with answers from a

Low-complexity: Sentence 1. "When the loop has rotated 180 degrees, the red half of the wire loop has rotated to the bottom and the yellow half of the wire loop has rotated to the top."

High-complexity: Sentence 7. "When the downward moving magnetic field intersects with the left-to-right moving electron flow on the yellow half of the wire loop (now on top), a force is exerted pushing electrons (and the yellow half of the wire loop) backwards away from where you are sitting."

Figure 2. Examples of low-complexity and high-complexity sentences in a lesson on how an electric motor works.

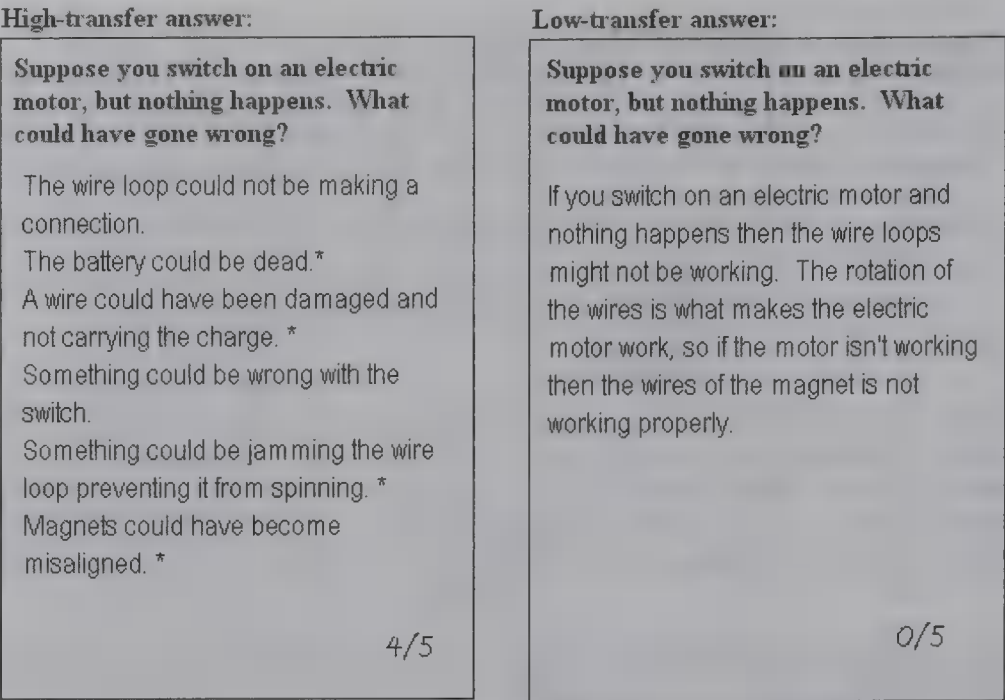

Figure 3. Examples of posttest answers from low-transfer and high-transfer students. Correct idea units are indicated by asterisks.

high-transfer student (in the left panel) and answers from a low-transfer student (in the right panel). Differences in transfer performance can be used to infer differences in germane processing during learning.

In this study, we examine the sensitivity of three commonly used techniques for measuring cognitive load—response time to a secondary task during learning, effort ratings during learning, and difficulty ratings after learning—to each of these three aspects of cognitive load. First, as shown in the first line of Table 2, we implemented a secondary task in our electric motor lesson. The secondary task was a visual monitoring task in which learners were asked to detect a periodic color change from pink to black in the background of the animation and to press the space bar as fast as possible each time this color change occurred. Response time has occasionally been used as a measure of cognitive load in multimedia research, with longer response times indicating greater cognitive load. When more cognitive resources are used by the primary task (learning from the narrated animation), fewer resources will be available to devote to the secondary task (noticing and responding to the background color change), resulting in a longer response time on the secondary task (Brünken, Steinbacher,

Schnotz, Plass, & Leutner, 2002; Chandler & Sweller, 1996; Marcus, Cooper, & Sweller, 1996; Sweller, 1988).

Second, as shown in the second line of Table 2, mental effort ratings were implemented in our electric motor lesson. We asked the learner to rate his or her current level of mental effort at points throughout the lesson on a 9-point scale ranging from 1 (*extremely low*) to 9 (*extremely high*). Self-reported mental effort ratings have been used somewhat more frequently in multimedia research than dual-task measurement of load (Paas et al., 2003; Paas & van Merriënboer, 1994; Paas, van Merriënboer, & Adam, 1994).

Third, as shown in the bottom line of Table 2, difficulty ratings were implemented in our electric motor lesson by asking the learner to make a retrospective judgment after the lesson concerning the lesson's difficulty, using a 9-point scale ranging from 1 (*extremely easy*) to 9 (*extremely difficult*). Self-reported difficulty ratings have been used somewhat less frequently in multimedia research (Kalyuga, Chandler, & Sweller, 1999; Mayer & Chandler, 2001).

A major goal of this study is to determine whether these three measures of cognitive load tap the same underlying construct (suggesting a unitary theory of cognitive load) or whether they are

Table 2  
Three Ways of Measuring Cognitive Load in Multimedia Learning

Type of measure	Implementation of measure
Response time to secondary task	At each of eight points in an animated narration, the background color slowly changes from pink to black, and the learner's task is to press the spacebar as soon as the background color changes.
Effort rating	At each of eight points in an animated narration the learner is asked to rate "your level of mental effort on this part of the lesson" on a 9-point scale ranging from 1 ( <i>extremely low mental effort</i> ) to 9 ( <i>extremely high mental effort</i> ).
Difficulty rating	At the end of the lesson, the learner is asked to rate "how difficult this lesson was" on a 9-point scale ranging from 1 ( <i>extremely easy</i> ) to 9 ( <i>extremely difficult</i> ).

sensitive to different manipulations of cognitive load (suggesting a model of cognitive load that is more consistent with a triarchic theory). According to a unitary theory of cognitive load, each of the three measures of cognitive load should be sensitive to each of the three types of cognitive load (i.e., indicating higher load for redundant vs. nonredundant groups, high-complexity vs. low-complexity sentences, and low-transfer vs. high-transfer learners), and the three should be highly correlated with one another. In other words, they should indicate one unitary measurement of cognitive load. According to a triarchic theory of cognitive load, it is possible that different measures of cognitive load may be sensitive to different types of cognitive load. If cognitive load is not a unitary construct and the measures are not all sensitive to the same type of load, then we should find that the three measures of cognitive load are not highly correlated with one another. If this is the case, the measures should be evaluated in terms of which aspect of the construct each measure best taps into. Predictions of possible ways in which the measures may relate to the three aspects of cognitive load in a triarchic theory are listed in Table 3. Alternatively, the possibility that the measures may gauge altogether different underlying constructs should be considered. We examined these questions in two experiments.

### Experiment 1

In Experiment 1, we tested the predictions of the unitary theory of cognitive load and the triarchic theory of cognitive load by examining the sensitivity of each of three common metrics of cognitive load—response time to a secondary task, mental effort rating, and difficulty rating—to manipulations intended to create differences in extraneous, intrinsic, and germane processing.

### Method

#### Participants and Design

The participants were 56 college students. There were 16 men and 40 women, and their ages ranged from 18 to 22. We used a  $2 \times 2$  mixed design with the between-subjects factor being redundancy (redundant vs. nonredundant lesson) and the within-subject factor being complexity (high- vs. low-complexity sentences within the lesson). Concerning redundancy, 28 participants served in the nonredundant group (in which they received a computer-based lesson containing animation and narration), and 28 participants served in the redundant group (in which they received the same computer-based lesson containing the animation and narration plus on-screen text). Concerning complexity, four of the sen-

tences in the lesson were identified as particularly high-complexity sentences (because they contained many interacting concepts), and four of the sentences in the lesson were identified as particularly low-complexity sentences (because they contained few interacting concepts). For each participant, cognitive load measurements were taken after each of the eight target sentences (for response time and effort rating) and after the entire lesson (for difficulty rating).

#### Materials and Apparatus

The computer-based materials consisted of a pretest questionnaire, a mental effort rating questionnaire, and two computer-based multimedia lessons on how an electric motor works. A Flash program designed for this experiment presented the multimedia lessons and collected data on the pretest questionnaire, response time to secondary tasks, and mental effort ratings. The paper-based materials consisted of a difficulty rating sheet and seven posttest problem sheets.

*Pretest questionnaire.* The computer-based pretest questionnaire assessed participants' previous experience with and knowledge about electronics and asked them to report their age, gender, SAT scores, and year in college.

*Multimedia lesson.* The nonredundant program (exemplified in the left portion of Figure 1) presented a narrated animation about how electric motors work that was used by Mayer, Dow, and Mayer (2003). The redundant version was identical except that it also presented on-screen text in paragraph form that was identical to the words spoken in the narration (as exemplified in the right panel of Figure 1). The on-screen text was redundant with the spoken narration, which is thought to increase extraneous cognitive load, reflected in lower scores on tests of transfer (Mayer, 2005b). Both versions of the lesson also included two levels of sentence complexity. We analyzed each sentence or clause in the script in terms of the number of interacting elements, or the number of idea units that must be kept in mind at one time for comprehension to take place. We then chose the four points of the lesson with the highest number of interacting elements, which we call *high sentence complexity*, and the four points with the lowest number of interacting elements, which we call *low sentence complexity*. We used these eight points during the lesson to implement the secondary task and the mental effort question.

The lesson was approximately 6 min long and described the cause-and-effect steps in the operation of an electric motor, which consisted of a battery, electrical wires, a commutator, a wire loop, and a pair of magnets.

*Secondary task and mental effort rating.* At eight points during the animation determined by the analysis of sentence complex-

Table 3  
Possible Relations Among Three Measures of Cognitive Load and Three Types of Cognitive Load

Type of measure	Type of cognitive load
Response time	Extraneous—When material includes redundant words, the learner wastes cognitive capacity, resulting in slower response times to a secondary task.
Effort rating	Intrinsic—When material is more complex, the learner must work harder to comprehend it, resulting in higher effort ratings.
Difficulty rating	Germane—Learners who perform well on the transfer test had capacity available for deeper processing during learning, reflected in lower difficulty ratings.

ity, the background color of the animation gradually changed from pink to black. Participants were instructed to press the space bar as quickly as they could when they saw the color begin to change. Four of the color changes occurred at the end of high-complexity sentences and four occurred at the end of low-complexity sentences. The program recorded the students' response times (RTs; in milliseconds) to press the space bar for each of the eight events and calculated an average RT for high-complexity sentences and low-complexity sentences for each student. When the student pressed the space bar, the program paused the animation and presented a question regarding the amount of mental effort the participant was currently experiencing. The question asked participants to "please rate your level of mental effort on this part of the lesson" and gave them a Likert-type scale ranging from 1 (*extremely low mental effort*) to 9 (*extremely high mental effort*) from which to choose their response. The program computed and recorded the mean effort rating for each student for the four high-complexity sentences and the four low-complexity sentences. After indicating their answer by clicking the corresponding rating, participants had a choice of two buttons to press: continue or replay. Although participants believed that these buttons allowed them to either replay the last section of the animation or to continue from where they left off, the buttons actually performed identical functions; they both replayed the last sentence and continued onward. All students opted for the continue button.

**Difficulty rating and posttest.** The difficulty rating scale consisted of a sheet of paper containing the instruction "Please indicate how difficult this lesson was by checking the appropriate answer"; response choices ranged from 1 (*extremely easy*) to 9 (*extremely difficult*). The posttest consisted of seven sheets of paper, each with a question printed at the top and space for participants to write their answers. The questions tested participants' ability to transfer information they had learned about electric motors to problem-solving situations and were identical to those used by Mayer et al. (2003). The questions were (a) "What could you do to increase the speed of the electric motor, that is, to make the wire loop rotate more rapidly?" (b) "What could you do to increase the reliability of the electric motor, that is, to make sure it would not break down?" (c) "Suppose you switch on an electric motor, but nothing happens. What could have gone wrong?" (d) "What could you do to reverse the movement of the electric motor, that is, to make the wire loop rotate in the opposite direction?" (e) "Why does the wire loop move?" (f) "If there was no momentum, how far would the wire loop rotate when the motor is switched on?" and (g) "What happens if you move the magnets further apart? What happens if you connect a larger battery to the wires? What happens if you connect the negative terminal to the red wire and the positive terminal to the yellow wire?"

**Apparatus.** The apparatus consisted of five Sony Vaio laptop computers with 15-in. screens and Panasonic headphones.

### Procedure

Participants were randomly assigned to the redundant or nonredundant group and were seated in a cubicle at a work desk with an individual laptop computer. There were between 1 and 5 participants in each session. Figure 4 summarizes the procedure. First, the experimenter briefly described the study, and each participant read and signed an informed consent form, which was collected by

the experimenter. Second, the experimenter logged the participants in on their respective computers and asked them to complete the pretest questionnaire presented on the computer screen. Next, participants read on-screen instructions about how to perform the secondary task, and then they completed a practice task. The practice task was identical to the experimental dual task, except that it presented an animation on an unrelated topic (i.e., how brakes work). After the practice task, the experimenter inquired as to whether all participants were comfortable with the task, and participants were given a chance to ask questions. Once all participants indicated that they fully understood the task, they continued on to the experimental phase of the experiment in which the electric motor lesson was presented. Participants in the redundant group received the redundant version and participants in the nonredundant group received the nonredundant version. After the lesson, participants were given the difficulty rating sheet to complete at their own pace, followed by each of the seven posttest sheets. The posttest questions were presented one at a time in the order indicated in the *Materials and Apparatus* section, and participants were given a limit of 3 min to write their answers to each question.

## Results and Discussion

### Scoring

RT measurements more than 3 standard deviations from the mean of any of the RT measurements were replaced with that participant's series mean, with respect to whether the outlying RT occurred at a high- or low-complexity sentence. We opted to replace the outlying RT rather than simply exclude each outlying RT or the entire participant, with the assumptions that a RT of more than 3 standard deviations above the mean indicated the participant's inattention and that averaging across that participant's low- or high-complexity trials (depending on the type of trial in which the outlier occurred) would provide a sufficient estimate of how that participant would have performed on that trial had he or she given the task the appropriate attention. In cases in which more than one RT was an outlier within a participant's series, that participant was excluded from further analysis because there was not enough information to make a sufficient estimate of RT on those trials. This resulted in 2 participants being excluded, leaving 26 in the redundant group and 28 in the nonredundant group ( $N = 54$ ).

Answers on the transfer test were coded for correct answers, out of a total possible 25. The list of acceptable answers was generated by Mayer et al. (2003). For example, the acceptable answers for the third question about what went wrong were "the wire loop is stuck," "the wire is severed or disconnected from the battery," "the battery fails to produce voltage," "the magnetic field does not intersect the wire loop," and "the wire loop does not make contact with the commutator." Students did not receive credit for vague answers, such as "Something is wrong with the battery," but did get credit for correct answers that were worded differently than in the lesson. For all but one question, there was more than one possible acceptable answer. Each acceptable answer generated by the participant earned 1 point; we summed the number of points across all of the questions to obtain a total transfer score, resulting in a range from 0 to 16 correct idea units, with a median of 6.5.

Experiment 1Experiment 2Both Experiments:

Figure 4. Summary of procedure.

Assignment to low- versus high-transfer groups was based on a median split in which students who scored 7 points or more were assigned to the high-transfer group ( $n = 27$ ) and students who scored 6 points or less were assigned to the low-transfer group ( $n = 27$ ).

*Response Time to the Secondary Task*

If response time to a secondary task during learning is a valid measure of cognitive load, it should differ on the basis of the manipulations thought to affect cognitive load. That is, response time should be longer for the redundant group than for the nonredundant group, on more complex sentences in the lesson than on less complex sentences, and for low-transfer learners than for high-transfer learners.

The first row of data in Table 4 shows the mean response times (and standard deviations), first for the redundant and nonredundant groups, second for the high- and low-complexity sentences, and finally for the low- and high-transfer learners. A box around two means (and their standard deviations) indicates that we found some difference between them, with bold lines indicating a significant

difference at  $p < .05$  and light lines indicating a nonsignificant difference (at  $p < .10$ ) but an effect size greater than .20. We conducted a 2 (redundant vs. nonredundant)  $\times$  2 (low- vs. high-complexity sentences) mixed analysis of variance (ANOVA), with redundancy as a between-subjects factor and complexity as a repeated-measures factor. First, there was a marginal main effect for redundancy, with the redundant group producing marginally higher response times to the secondary task than the nonredundant group,  $F(1, 52) = 3.77, p = .06, d = .53$ . Although this trend was not statistically significant, the effect size is in the medium range, which suggests that the lack of significance may have been the result of a small sample size (Cohen, 1988). Second, there was a marginal main effect for complexity, with high-complexity sentences requiring marginally longer RTs to the secondary task than did low-complexity sentences,  $F(1, 52) = 3.85, p = .06, d = .25$ . Again, we note that although this trend was not statistically significant, the effect size was in the small range. No significant interaction was found between complexity and redundancy,  $F(1, 52) = 0.004, ns$ . Third, a  $t$  test revealed that students who scored low on transfer performance did not differ significantly on re-

Table 4  
Means (and Standard Deviations) for Three Types of Cognitive Load Manipulations Based on Three Measures of Cognitive Load:  
Experiment 1

Measure of cognitive load	Type of cognitive load					
	Extraneous load: Redundancy (Which cognitive load measure(s) is sensitive to redundancy?)		Intrinsic load: Complexity (Which cognitive load measure(s) is sensitive to sentence complexity?)		Germane load: Transfer (Which cognitive load measure(s) is sensitive to transfer performance?)	
	Redundant	Nonredundant	High	Low	High ( <i>n</i> = 27)	Low ( <i>n</i> = 27)
Response time (ms)	2,657 (825)	2,249 (719)	2,555 (1,035)	2,337 (714)	2,477 (933)	2,414 (636)
Effort rating	4.97 (1.54)	5.49 (1.41)	5.43 (1.55)	5.05 (1.50)	5.30 (1.57)	5.18 (1.42)
Difficulty rating	5.15 (1.54)	5.36 (1.47)			4.63 (1.39)	5.89 (1.34)

Note. *N* = 54. Boxes with bold lines indicate significant difference ( $p < .05$ ). Boxes with light lines indicate  $.05 < p < .10$  and effect size greater than  $d = .20$ .

sponse time compared with students who scored high on transfer performance,  $t(52) = -0.29$ , *ns*. We furthermore computed a Cronbach's alpha for the four RTs at low-complexity points in the lesson and for the four RTs at high-complexity points to investigate the internal reliability of this measurement. Although the low-complexity points showed a low reliability ( $\alpha = .33$ ), high-complexity points were shown to be reliable ( $\alpha = .70$ ).

#### Mental Effort Ratings During Learning

For self-reported mental effort during a lesson to be considered a valid measure of cognitive load, several conditions should be met. First, lessons containing animation with redundant text and narration should cause learners to rate their mental effort higher overall than nonredundant lessons containing only animation and narration. Second, learners should rate their mental effort significantly higher at difficult (high-complexity) points in the lesson than at simpler (low-complexity) points in the lesson. Third, students who score low on transfer should rate their mental effort significantly higher overall than those who score high on transfer (alternatively, higher effort may indicate more germane processing, which should lead to higher scores on the transfer test).

The second row of data in Table 4 shows the mean mental effort ratings (and standard deviations) for each of three comparisons, first for the redundant and nonredundant groups, second for the high- and low-complexity sentences, and last for the low- and high-transfer learners. We conducted a 2 (redundant vs. nonredundant)  $\times$  2 (high- vs. low-complexity sentences) mixed ANOVA, with redundancy as a between-subjects factor and complexity as a repeated-measures factor. First, there was no significant effect for redundancy, with the redundant group and the nonredundant group rating their mental effort equivalently,  $F(1, 52) = 1.67$ , *ns*. Second, in contrast, there was a significant main effect of complexity in which participants rated their mental effort as higher on high-complexity sentences than on low-complexity sentences,  $F(1, 52) = 17.78$ ,  $p < .001$ ,  $d = .25$ . No significant interaction was found between redundancy and complexity,  $F(1, 52) = 0.004$ , *ns*. Third, a *t* test revealed that students who scored low on transfer performance did not differ significantly on mental effort ratings than students who scored high on transfer performance,  $t(52) =$

$-0.30$ , *ns*. Cronbach's alpha indicated that measures of mental effort were reliable both at low-complexity points ( $\alpha = .84$ ) and at high-complexity points ( $\alpha = .90$ ).

#### Overall Difficulty Ratings After Learning

The last row of data in Table 4 shows the mean lesson difficulty ratings (and standard deviations) for each of two comparisons: between the redundant and nonredundant groups and between the low-transfer and high-transfer learners. There were no separate difficulty ratings for low and high complexity because this rating was only administered at the end of the lesson. If the difficulty rating is a valid measure of cognitive load, then the mean difficulty ratings should differ between redundant and nonredundant versions of that lesson. In addition, the mean difficulty rating of the low-transfer group should be greater than the mean difficulty rating of the high-transfer group. Finally, although we would expect learners to rate high-complexity sentences as more difficult than low-complexity sentences, there was no way to examine this because difficulty ratings were solicited only for the entire lesson after learning.

First, a *t* test showed that ratings of difficulty did not differ between the redundant and nonredundant groups,  $t(52) = 0.50$ ,  $p = .62$ , which could indicate either that this rating scale is not sensitive to changes in extraneous load or that the redundant version of the multimedia lesson created no more cognitive load than the nonredundant version. The results of a second *t* test revealed that those who scored lower on the transfer test tended to rate the lesson as more difficult than those who scored higher,  $t(52) = 3.39$ ,  $p < .001$ ,  $d = .92$ .

#### Are Commonly Used Metrics of Cognitive Load Related to One Another?

If all of the methods we used to measure cognitive load did indeed measure the same construct, then we would expect to see significant correlations among all of the measures. Specifically, we would expect response time on a secondary task, self-reported mental effort, and difficulty rating to all be positively correlated. As shown in Table 5, however, we did not find this pattern of

Table 5  
Correlation Matrix of Dependent Measures for Both Groups:  
Experiment 1

Measure	1	2	3	4
1. Dual-task reaction time	—	.27*	.20	.07
2. Self-report mental effort		—	.26	.19
3. Lesson difficulty rating			—	-.22
4. Score on transfer test				—

Note.  $N = 54$ .

\*  $p < .05$ .

correlations. Of the six pairwise correlations, only one reached statistical significance; response time on the secondary task was significantly correlated with mental effort ( $r = .27$ ,  $p = .05$ ), but at a modest level. The correlation results do not support the contention that various cognitive load measures tend to measure the same thing, as proposed by the unitary theory of cognitive load.

#### Are Different Cognitive Load Measures Sensitive to Different Types of Cognitive Load?

Table 6 shows whether each cognitive load measure detected a significant difference for each type of cognitive load and the effect size indicated by each measure for each type of load. The pattern that emerges from these results suggests that each of the three measures—response time, effort rating, and difficulty rating—was sensitive mainly to one aspect of cognitive load. Response times were most sensitive to redundancy (which was intended to create extraneous cognitive processing), effort ratings during learning were most sensitive to complexity (which was intended to create intrinsic cognitive processing), and difficulty ratings after learning were most sensitive to transfer performance (which was intended to tap germane processing). Given the distinct pattern that was generated in Experiment 1, it is worthwhile to determine whether the pattern could be replicated in a similar study.

Overall, these commonly used measures of cognitive load do not appear to be related to one another in a clear-cut fashion. In contrast, the pattern of the results suggests that these measures may be tapping different aspects of cognitive load or different constructs altogether. The results are more consistent with the triarchic theory of cognitive load than with a unitary theory of cognitive load.

Table 6  
Effect Sizes for Three Types of Cognitive Load Manipulation Created Based on Three Measures of Cognitive Load

Measure of cognitive load	Type of cognitive load					
	Extraneous load (redundant vs. nonredundant)		Intrinsic load (high vs. low complexity)		Germane load (high vs. low transfer)	
	Exp. 1	Exp. 2	Exp. 1	Exp. 2	Exp. 1	Exp. 2
Response time	.53 <sup>†</sup>	.48*	.25 <sup>†</sup>	<i>ns</i>	<i>ns</i>	<i>ns</i>
Effort rating	<i>ns</i>	.35*	.25**	.16**	<i>ns</i>	<i>ns</i>
Difficulty rating	<i>ns</i>	<i>ns</i>			.92**	.48*

Note. Cohen's  $d$  is the measure of effect size. Difficulty rating does not apply to intrinsic load. Exp. = Experiment.

<sup>†</sup>  $p < .10$ . \*  $p < .05$ . \*\*  $p < .01$ .

## Experiment 2

In Experiment 1, an interesting pattern of results emerged in which each of the three measures of cognitive load tended to be sensitive to a different aspect of cognitive load. However, the many measures of cognitive load may have been somewhat intrusive to the learning task, resulting in measures that may reflect distraction rather than cognitive load per se. To encourage learners to focus on deep cognitive processing as their goal, in Experiment 2 we provided learners with *pretest questions* that we asked them to be able to answer at the end of the lesson. These pretest questions were shown by Mayer et al. (2003) to improve scores on the transfer test for this lesson. We reasoned that if students were more motivated to learn the information, they would pay closer attention to the lesson and therefore provide more valid measurements of cognitive load.

### Method

#### Participants and Design

Participants in Experiment 2 were 99 college students (33 male, 66 female) ranging in age from 17 to 22. Half of the participants were randomly assigned to the nonredundant group ( $n = 49$ ) and half to the redundant group ( $n = 50$ ). The design of Experiment 2 was identical to that of Experiment 1.

#### Materials, Apparatus, and Procedure

The materials, apparatus, and procedure of this experiment were identical to those of Experiment 1, with the addition of two pretest questions. The pretest questions provided the participants with knowledge about the type of information they were expected to learn during the lesson. They were presented on an 8.5- × 11-in. sheet before the lesson and consisted of Questions a and b from the transfer test (i.e., "What could you do to increase the speed of the electric motor, that is, to make the wire loop rotate more rapidly?" and "What could you do to increase the reliability of the electric motor, that is, to make sure it would not break down?"). Participants were told that the pretest questions were "representative of the types of questions that would be asked later." Participants were allowed to look over the pretest question sheet until they felt comfortable with the material, at which time they handed the sheet back to the experimenter. Then the experimenter reminded participants of the instructions, answered any questions, and instructed

them to begin the computer program. From this point on, the procedure was identical to Experiment 1.

Results

Scoring

Outlying RTs to the secondary task were dealt with in the same manner as in Experiment 1. Again, participants who had more than two outlying RTs in a series were excluded from further analyses. This resulted in the exclusion of only 3 participants, leaving 47 in the nonredundant group and 49 in the redundant group ( $N = 96$ ). Answers on the transfer test were coded in the same fashion as in Experiment 1.

Scores on the transfer test ranged from 0 to 13 correct idea units, with a median of 6.0, out of a possible total of 25. A subset of the data was coded by a second rater, resulting in a correlation of .772 ( $p = .009$ ). A median split resulted in 45 high scorers (scoring 7 points or more) and 51 low scorers (scoring 6 points or less).

RT to the Secondary Task

As in Experiment 1, we expected RT on the secondary task to be longer for the redundant group than for the nonredundant group, longer for high-complexity sentences in the lesson than for low-complexity sentences, and longer for low-transfer learners than for high-transfer learners.

The first row of data in Table 7 shows the mean RTs (and standard deviations) for three comparisons, first for the redundant and nonredundant groups, second for the high- and low-complexity sentences, and last for the low- and high-transfer learners. As in Table 4, a box around two means (and their standard deviations) indicates that we found some difference between them, with bold lines indicating a significant difference. We conducted a 2 (redundant vs. nonredundant)  $\times$  2 (low vs. high complexity) mixed ANOVA with redundancy as a between-subjects factor and complexity as a repeated measures factor. There was a significant main effect for redundancy, with the redundant group producing longer RTs than the nonredundant group,  $F(1, 94) = 5.44, p = .02, d = .48$ . However, no main effect of complexity was found,  $F(1, 94) = 1.67, ns$ , nor was there a significant interaction between trial type and redundancy,  $F(1,$

94) = 0.93, *ns*. These results show that redundant on-screen text caused longer RTs and indicate that participants who saw the nonredundant version had more free cognitive resources. However, unlike in Experiment 1, RT did not appear to be sensitive to the number of interacting elements (i.e., sentence complexity) at a given point in the lesson. Finally, a *t* test showed that there was no significant difference between low- and high-transfer learners on their RTs to the secondary task,  $t(94) = 1.68, ns$ . Cronbach's alpha showed internal reliability for RT measurements both at low-complexity points ( $\alpha = .79$ ) and at high-complexity points ( $\alpha = .76$ ).

Mental Effort Rating During Learning

As in Experiment 1, on the basis of unitary theory, we expected mental effort ratings to be higher (indicating more mental effort expended) for the students learning from the redundant lesson than for those learning from the nonredundant lesson. We also expected learners to rate their mental effort higher at difficult (high-complexity) sentences in the lesson than at easier (low-complexity) sentences in the lesson. Finally, we expected that learners who scored low on the transfer test would rate their mental effort higher overall than those who scored high on the transfer test.

The second row of data in Table 7 shows the mean RTs (and standard deviations) for three comparisons, first for the redundant and nonredundant groups, second for the high- and low-complexity sentences, and last for the low- and high-transfer learners. We conducted a 2 (redundant vs. nonredundant)  $\times$  2 (high vs. low complexity) mixed ANOVA with redundancy as a between-subjects factor and trial type as a repeated measures within-subjects factor. First, unlike in Experiment 1, ratings of mental effort differed significantly between the redundant and nonredundant lessons,  $F(1, 94) = 4.17, p = .04, d = .35$ . Second, we again found a significant main effect of complexity; learners rated their mental effort as higher on high-complexity sentences than on low-complexity sentences,  $F(1, 94) = 20.36, p < .001, d = .16$ . No significant interaction of complexity and redundancy was found,  $F(1, 94) = 0.21, ns$ . Third, a *t* test showed that learners who scored low on the transfer test had overall mental effort ratings similar to those who scored high on the transfer test,

Table 7  
Means (and Standard Deviations) for Three Types of Cognitive Load Manipulations Based on Three Measures of Cognitive Load: Experiment 2

Measure of cognitive load	Type of cognitive load					
	Extraneous load: Redundancy (Which cognitive load measure(s) is sensitive to redundancy?)		Intrinsic load: Complexity (Which cognitive load measure(s) is sensitive to sentence complexity?)		Germane load: Transfer (Which cognitive load measure(s) is sensitive to transfer performance?)	
	Redundant	Nonredundant	High	Low	High ( $n = 45$ )	Low ( $n = 51$ )
Response time (ms)	2,918 (872)	2,520 (797)	2,677 (869)	2,769 (974)	2,569 (848)	2,859 (847)
Effort rating	5.67 (1.59)	4.99 (1.67)	5.47 (1.66)	5.21 (1.68)	5.58 (1.58)	5.13 (1.71)
Difficulty rating	5.33 (1.83)	5.21 (1.74)			4.82 (1.92)	5.67 (1.56)

Note. Boxes with bold lines indicate significant difference ( $p < .05$ ).

$t(94) = -1.31$ , *ns*. Cronbach's alpha showed internal reliability for mental effort measurements both at low-complexity points ( $\alpha = .90$ ) and at high-complexity points ( $\alpha = .90$ ).

### Overall Difficulty Rating After Learning

As in Experiment 1, according to the unitary theory, we expected learners in the redundant group to rate the difficulty of the lesson as higher than those in the nonredundant group. In addition, we expected that learners who scored low on the transfer test would rate the lesson as more difficult than those who scored high.

The last row of data in Table 7 shows the mean lesson difficulty ratings (and standard deviations) for two comparisons—for the redundant and nonredundant groups and for the low- and high-transfer learners. There were no separate difficulty rating scores for low and high complexity because this rating was only administered at the end of the lesson. First, there was no significant difference between the redundant and nonredundant groups; learners in both groups rated the difficulty of the lesson similarly,  $t(94) = -0.31$ , *ns*. In contrast, there was a significant difference between high- and low-transfer learners; learners who scored low on the transfer test tended to rate the lesson as more difficult than those who scored high,  $t(94) = 2.38$ ,  $p = .02$ ,  $d = .48$ .

### Are Commonly Used Metrics of Cognitive Load Related to One Another?

Table 8 shows the correlations among the dependent variables. If these methods are all measuring a unitary or overall level of cognitive load, we would expect them all to be significantly positively correlated with one another. However, RT to the secondary task was not positively correlated with any of the other measures of cognitive load. It was, however, significantly negatively correlated with scores on the transfer test ( $r = -.30$ ,  $p = .003$ ), indicating that participants who scored lower on the transfer test tended to take longer to respond to the secondary task, which is the result we would expect if cognitive load were causing a slower RT. Mental effort ratings were positively correlated with difficulty ratings ( $r = .33$ ,  $p = .001$ ) but with no other measure. Difficulty ratings were negatively correlated with transfer scores ( $r = -.22$ ,  $p = .03$ ) but with no other measure. As can be seen by comparing Tables 5 and 8, the measures were more correlated with one another in Experiment 2 than in Experiment 1, but most of the relations were weak or nonsignificant.

Table 8  
Correlations Between Dependent Measures for Both Groups:  
Experiment 2

Measure	1	2	3	4
1. Dual-task reaction time	—	.12	.13	-.30**
2. Self-reported mental effort		—	.33**	.11
3. Lesson difficulty rating			—	-.22*
4. Score on transfer test				—

Note.  $N = 96$ .  
\*  $p < .05$ . \*\*  $p < .01$ .

### Are Different Cognitive Load Measures Sensitive to Different Types of Cognitive Load?

Table 6 shows whether each cognitive load measure detected a significant difference for each type of cognitive load and the effect size indicated by each cognitive load measure for each type of cognitive load. The pattern of results for Experiment 2 is quite similar to that in Experiment 1.

In Experiment 2, it was again apparent that RTs on the secondary task were most sensitive to redundancy than to other manipulations of cognitive load. Because redundancy was intended to create extraneous cognitive load, we can conclude that RTs were most sensitive to differences in extraneous load. Ratings of mental effort were most sensitive to the complexity of the sentences, which was intended to create intrinsic cognitive load. Finally, ratings of the overall difficulty of the lesson were most sensitive to differences in the learning outcomes of the students, in terms of their scores on the transfer test, which is an indication of germane cognitive load. Taken together with the findings from Experiment 1, these results show that these measures are tapping separable aspects of cognitive load.

### Conclusion

#### Summary of Results

Across two experiments, we found that different measures of cognitive load were sensitive to different types of cognitive load: (a) RT to the secondary task was most sensitive to manipulations of extraneous processing (reflected in longer RTs for the redundant group than for the nonredundant group), (b) effort ratings during learning were most sensitive to manipulations of intrinsic processing (reflected in higher effort attributed to high-complexity sentences than to low-complexity sentences), and (c) difficulty ratings after learning were most sensitive to differences related to germane processing (reflected in higher difficulty reported by low-transfer learners than by high-transfer learners). In both experiments, we also found that different measures of cognitive load were not highly correlated with one another. This work is consistent with recent findings reported by Ayres (2006), in which a subjective rating measure administered after each problem was sensitive to differences in intrinsic processing, and by Brünken, Plass, and Leutner (2004), in which a dual-task measure was sensitive to differences in extraneous processing.

#### Theoretical Implications

If cognitive load is a unitary construct, reflecting an overall amount of cognitive resources allocated to the task, all types of manipulations of the learning situation (be it a manipulation of the study materials or of the motivation of the learner, etc.) should cause a corresponding change in the amount of load, and all measures that are directly related to cognitive load should correlate with one another. However, if cognitive load is composed of, or influenced by, different elements, as proposed by Sweller (1999) and Mayer (2001), then different manipulations of the learning situation can cause different types of cognitive load to vary in distinguishable ways. In this case, it may be possible that some measures are more sensitive to one type of change in cognitive load than to others.

On the theoretical side, this pattern of results is most consistent with a triarchic theory of cognitive load, in which cognitive processing during learning is analyzed into three capacity-demanding components—extraneous processing, intrinsic (or essential) processing, and germane (or generative) processing. More important, this study provides empirical support, replicated across two experiments, for a dissociation among these three types of cognitive load. The results are not consistent with a unitary theory of cognitive load, which focuses on the overall amount of cognitive processing during learning.

### Practical Implications

On the practical side, the results provide some validation for each of the three measures of cognitive load—RT to a secondary task, mental effort rating during learning, and difficulty rating made retrospectively immediately following learning—because each measure was sensitive to a particular cognitive load manipulation. An important practical implication is that different measures of cognitive load should not be assumed to measure overall cognitive load, but may be effectively used to measure different types of cognitive load. In particular, when the goal is to assess the level of extraneous cognitive load, RT to a secondary task appears to be most appropriate; when the goal is to assess the level of intrinsic cognitive load, mental effort ratings during learning may be most appropriate; and when the goal is to detect the learner's level of germane cognitive load, a simple difficulty rating immediately after learning may prove most useful.

### Limitations and Future Directions

Although a similar pattern of results was obtained across two experiments, there is still a need for replication studies involving different instructional materials and different learners. It is possible that given different learning materials or different learner characteristics, we may find a different pattern of results. Regarding the intercorrelation of the measures in the two experiments, it is possible that we found mostly small, nonsignificant effects in Experiment 1 because of a small sample size, but this argument does not hold for Experiment 2 because the sample size was nearly double.

Consistent with research on the expertise reversal effect (Kalyuga, 2005), we suspect that the pattern of results might depend on the prior knowledge of the learner. In our experiments, the learners generally had low prior knowledge, so we suggest that future research should also take the learner's level of prior knowledge into account.

In this study, we focused on three specific measures of cognitive load, but there are alternative ways to implement each measure and there are certainly other measures of cognitive load. Similarly, we examined three cognitive load manipulations, but alternative methods of manipulating cognitive load should still be investigated using similar measures of load.

One problem with the current study is that the various measures of cognitive load were somewhat intrusive and may have created an unnatural learning situation. Finding unobtrusive and valid measures of each type of cognitive load continues to be a challenge for multimedia researchers. However, this challenge is worth meeting because the concept of cognitive load plays a central role in most theories of instructional design.

Received December 12, 2006

Revision received August 22, 2007

Accepted September 4, 2007 ■

The main purpose of the *Journal of Educational Psychology* is to publish original, primary psychological research pertaining to education across all ages and educational levels. A secondary purpose of the *Journal* is the occasional publication of exceptionally important theoretical and review articles that are pertinent to educational psychology.

**Manuscript preparation.** Authors should prepare manuscripts according to the *Publication Manual of the American Psychological Association* (5th ed.). Manuscripts may be copyedited for bias-free language (see chap. 2 of the *Publication Manual*). Formatting instructions (all copy must be double-spaced) and instructions on the preparation of tables, figures, references, metrics, and abstracts appear in the *Manual*. For APA's Checklist for Manuscript Submission, see [www.apa.org/journals](http://www.apa.org/journals). **Abstract and key-words.** All manuscripts must include an abstract containing a maximum of 180 words typed on a separate page. After the abstract, please supply up to five keywords or brief phrases. **References.** References should be listed in alphabetical order. Each listed reference should be cited in text, and each text citation should be listed in the References. Basic formats are as follows:

- Haag, L., & Stern, E. (2003). In search of the benefits of learning Latin. *Journal of Educational Psychology*, 95, 174–178.
- Bollen, K. A. (1989). *Structural equations with latent variables*. New York: Wiley.
- Johnson, D. W., & Johnson, R. T. (1990). Cooperative learning and achievement. In S. Sharon (Ed.), *Cooperative learning: Theory and research* (pp. 173–202). New York: Praeger.

Adequate description of participants is critical to the science and practice of educational psychology; this allows readers to assess the results, determine generalizability of findings, and make comparisons in replications, extensions, literature reviews, or secondary data analyses. Authors should see guidelines for sample-subject description in the *Manual*. Appropriate indexes of effect size or strength of relationship should be incorporated in the results section of the manuscript (see pp. 5, 25–26 of the *Manual*). Information that allows the reader to assess not only the significance but also the magnitude of the observed effects or relationships clarifies the importance of the findings. **Figures.** Graphics files are welcome if supplied as Tiff, EPS, or PowerPoint. High-quality printouts or glossies are needed for *all* figures. The minimum line weight for line art is 0.5 point for optimal printing. When possible, please place symbol legends below the figure image instead of to the side. Original color figures can be printed in color at the editor's and publisher's discretion provided the author agrees to pay \$255 for one figure, \$425 for two figures, \$575 for three figures, \$675 for four figures, and \$55 for each additional figure.

**Publication policies.** APA policy prohibits an author from submitting the same manuscript for concurrent consideration by two or more publications. APA policy regarding posting articles on the Internet may be found at [www.apa.org/journals](http://www.apa.org/journals). In addition, it is a violation of APA Ethical Principles to publish "as original data, data that have been previously published" (Standard 8.13). As this is a primary journal that publishes original material only, APA policy prohibits publication of any manuscript or data that have already been published in whole or substantial part elsewhere. Authors have an obligation to consult journal editors concerning prior publication of any data on which their article depends. In addition, APA Ethical Principles specify that "after research

results are published, psychologists do not withhold the data on which their conclusions are based from other competent professionals who seek to verify the substantive claims through reanalysis and who intend to use such data only for that purpose, provided that the confidentiality of the participants can be protected and unless legal rights concerning proprietary data preclude their release" (Standard 8.14). Authors must have available their data throughout the editorial review process and for at least 5 years after the date of publication.

**Masked review policy.** Because the *Journal* has a masked review policy, authors submitting manuscripts are required to include, with each copy of the manuscript, a cover sheet that shows the title of the manuscript, the authors' names and institutional affiliations, the date the manuscript is submitted, and footnotes identifying the authors or their affiliations. The first page of the manuscript should omit the authors' names and affiliations but should include the title of the manuscript and the date it is submitted. Every effort should be made by the authors to see that the manuscript itself contains no clues to their identities. Authors are required to state in writing that they have complied with APA ethical standards in the treatment of their sample, or to describe the details of treatment. A copy of the APA Ethical Principles may be obtained at [www.apa.org/ethics/](http://www.apa.org/ethics/) or by writing the APA Ethics Office, 750 First Street, NE, Washington, DC 20002-4242. APA requires authors to reveal any possible conflict of interest in the conduct and reporting of research (e.g., financial interests in a test procedure, funding by pharmaceutical companies for drug research). Authors of accepted manuscripts will be required to transfer copyright to APA.

**Permissions.** Authors of accepted papers are required to obtain and provide to the editor on final acceptance all necessary permissions to reproduce in print and electronic form any copyrighted work, including, for example, test materials or portions thereof and photographs of people.

**Supplemental materials.** APA can now place supplementary materials online, which will be available via the published article in the PsycARTICLES database. To submit such materials, please see [www.apa.org/journals/authors/suppmaterial.html](http://www.apa.org/journals/authors/suppmaterial.html) for details. Authors of accepted papers will be asked to work with the editor and production staff to provide supplementary materials as appropriate.

**Submission.** Authors should submit their manuscripts electronically via the Manuscript Submission Portal at [www.apa.org/journals/edu](http://www.apa.org/journals/edu) (follow the link "Submit Manuscripts Electronically"). A checklist for manuscript submission, including guidelines for preparing the electronic file, can be found at [www.apa.org/journals/](http://www.apa.org/journals/). Correspondence regarding manuscripts should be sent to the Editor, Art Graessen, University of Memphis, Journal of Educational Psychology, 202 Psychology Building, Memphis, TN 38152-3230. In addition to addresses and phone numbers, authors should supply e-mail addresses, as most communications will be by e-mail. Fax numbers, if available, should also be provided for potential use by the editorial office and later by the production office. Authors should keep a copy of the manuscript to guard against loss. E-mail correspondence may be addressed to [jedgar@memphis.edu](mailto:jedgar@memphis.edu).

**Preparing files for production.** If your manuscript is accepted for publication, please follow the guidelines for file formats and naming provided at [www.apa.org/journals/authors/preparing\\_files.html](http://www.apa.org/journals/authors/preparing_files.html). If your manuscript was mask reviewed, please ensure that the final version for production includes a byline and full author note for typesetting.

# SHY CHILDREN, PHOBIC ADULTS

Nature and Treatment of Social Anxiety Disorder, Second Edition

Deborah C. Beidel and Samuel M. Turner

**T**his book describes the clinical presentation of social anxiety disorder, presents theoretical perspectives on its etiology, and examines the latest empirical data with respect to both pharmacological and behavioral interventions. Social anxiety disorder occurs in children, adolescents, and adults, but its manifestation and treatment differ depending on developmental factors. Drawing from a broad literature base as well as their extensive clinical experience, the authors illustrate the impact of developmental stage on all aspects of the disorder. They also provide practical implementation guidelines, enhanced by case examples, tips on patient management, lists of assessment instruments, and sample forms to use with clients.

Since publication of the first edition in 1998, knowledge about social anxiety disorder has advanced on several fronts. The new edition includes information from new studies differentiating patterns of distress characteristic of social anxiety disorder vs. social phobia. It draws on more substantive data bases to support firmer conclusions about the presentation of social anxiety disorder among children and adolescents as well as across various ethnocultural groups. New assessment strategies reviewed in this book include neuroassessments using magnetic resonance imaging, and well-validated self-report instruments and clinician rating scales. Authors review greatly expanded literature addressing pharmacological treatment and psychosocial treatments. New case descriptions and clinical materials are also included. This highly informative and comprehensive volume will be illuminating reading for practitioners, researchers, and students. 2007. 408 pages. Hardcover.

**CONTENTS:** Dedication ■ Acknowledgments ■ Preface ■ Introduction ■ Chapter 1. Clinical Presentation of Social Anxiety Disorder in Adults ■ Chapter 2. Clinical Presentation of Social Anxiety Disorder in Children and Adolescents ■ Chapter 3. Prevalence of Social Anxiety Disorder ■ Chapter 4. Etiology of Social Anxiety Disorder ■ Chapter 5. Assessment of Social Anxiety Disorder ■ Chapter 6. Managing Patients with Social Anxiety Disorder (and Their Parents) ■ Chapter 7. Pharmacological Treatment of Social Anxiety Disorder ■ Chapter 8. Behavioral and Cognitive-Behavioral Treatment of Social Anxiety Disorder in Adults ■ Chapter 9. Behavioral and Cognitive-Behavioral Treatment of Social Anxiety Disorder in Children and Adolescents ■ Epilogue ■ References ■ About the Authors

## The Information You Need May Be on the Internet, But Can You Find It?

There's a vast universe of information available on the Internet today.

With such abundance, how do you get to the most critical and highest quality content you need for your research or studies? Many general search engines simply don't allow you to target reliable scholarly literature.

There's a simple solution —thanks to your institution's library.

When you are looking for specific resources from PubMed or APA journals, for example, log into your university library system first. You can search an enormous array of authoritative, professional information sources—such as APA's five electronic databases—because your library has purchased subscriptions. And while you're on the Web, you take your library's rights with you, giving you access to more sites and more content.

Plus, you can use your library's online gateway from your home or office to get the information you need ***free of charge*** and ***around the clock***.

Problem solved.

ASSOCIATION

**C**hildhood Mental Health Disorders is a comprehensive report, based on a thorough review of the literature, of the current recognized spectrum of childhood mental health disorders, including effective use of psychotropic medications and psychosocial interventions for children and adolescents. All of the studies come from top experts in the medical and psychology communities, and include the most recent, updated information, despite the rapidly changing face of child and adolescent mental health studies. Acknowledging the complexity of these disorders and the need to individualize treatment, the volume is intended as a basic yet comprehensive framework for anyone interested in mental health in children and adolescents. The disorders addressed include attention deficit/hyperactivity disorder, obsessive-compulsive disorder, autism and schizophrenia, and other commonly recognized disorders.

The main purpose of the *Journal of Educational Psychology* is to publish original, primary psychological research pertaining to education across all ages and educational levels. A secondary purpose of the *Journal* is the occasional publication of exceptionally important theoretical and review articles that are pertinent to educational psychology.

**Change of Address:** Send change of address notice and a recent mailing label to the attention of Subscriptions Department, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee periodicals forwarding postage.

**Single Issues, Back Issues, and Back Volumes:** For information regarding single issues, back issues, or back volumes, write to Order Department, American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242.

**Microform Editions:** For information regarding microform editions, write to University Microfilms, Ann Arbor, MI 48106.

**Manuscripts:** Submit manuscripts electronically through the Manuscript Submissions Portal found at [www.apa.org/journals/edu](http://www.apa.org/journals/edu), according to the Instructions to Authors found elsewhere in this issue (see table of contents). Correspondence regarding manuscripts should be sent to the Editor, Karen R. Harris, Vanderbilt University, *Journal of Educational Psychology*, Box 507 Peabody College, Nashville, Tennessee 37203-5721. The opinions and statements published are the responsibility of the authors, and such opinions and statements do not necessarily represent the policies of APA or the views of the Editor.

**Copyright and Permission:** Those who wish to reuse APA-copyrighted material in a non-APA publication must secure from APA and the author of the material written permission to reproduce a journal article in full or journal text of more than 500 words. APA normally grants permission contingent on permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of \$25 per page. Permission from APA and fees are waived for those who wish to reproduce a single table or figure from a journal for use in a print product, provided the author's permission is obtained and full credit is given to APA as copyright holder and to the author through a complete citation. (Requesters requiring written permission for commercial use of a single table or figure will be assessed a \$25 service fee.) Permission and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use more than a single table or figure of their own material commercially (but for use in edited books, fees are waived for the author only if serving as the book editor). Permission and fees are waived for the photocopying of isolated journal articles for nonprofit classroom or library reserve use by instructors and educational institutions. A permission fee may be charged to the requester if students are charged for the material, multiple articles are copied, or large-scale copying is involved (e.g., for course packs). Access services may use unedited abstracts without the permission of APA or the author. Libraries are permitted to photocopy beyond the limits of the U.S. copyright law: (1) post-1977 articles, provided the per-copy fee in the code for this journal (0022-0663/08/\$12.00) is paid through the Copyright Clearance Center, 222 Rosewood Drive, Danvers, MA 01923; (2) pre-1978 articles, provided that the per-copy fee stated in the Publishers' Fee List is paid through the Copyright Clearance Center. Address requests for reprint permission to Permissions Office, American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242.

**Electronic Access:** APA members who subscribe to this journal have automatic access to a 3-year file of the journal in the PsycARTICLES® full-text database. See <http://member-sapa.org/access>.

**Reprints:** Authors may order reprints of their articles from the printer when they receive proofs.

**APA Journal Staff:** Susan J. A. Harris, *Senior Director, Journals Program*; Skip Maier, *Director, Journal Services*; Paige W. Jackson, *Director, Editorial Services*; Clark Munsell, *Account Manager*; Jodi Ashcraft, *Director, Advertising Sales and Exhibits*.

The **Journal of Educational Psychology** (ISSN 0022-0663) is published quarterly (February, May, August, November) in one volume per year by the American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242. Subscriptions are available on a calendar year basis only (January through December). The 2008 rates follow: *Nonmember Individual*: \$161 Domestic, \$185 Foreign, \$195 Air Mail. *Institutional*: \$450 Domestic, \$491 Foreign, \$504 Air Mail. *APA Member*: \$73. Write to Subscriptions Department, American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242. Printed in the U.S.A. Periodicals postage paid at Washington, DC, and at additional mailing offices. POSTMASTER: Send address changes to the *Journal of Educational Psychology*, American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242.

# Socioeconomic Differences in Reading Trajectories: The Contribution of Family, Neighborhood, and School Contexts

Nikki L. Aikens  
Mathematica Policy Research, Inc.

Oscar Barbarin  
University of North Carolina at Chapel Hill

In the present study, the authors use the Early Childhood Longitudinal Study, Kindergarten Cohort of 1998–1999, to examine the extent to which family, school, and neighborhood factors account for the impact of socioeconomic status (SES) on children's early reading. Through the use of hierarchical linear modeling techniques, growth curve models were estimated to depict children's reading trajectories from kindergarten to 3rd grade. Family characteristics made the largest contribution to the prediction of initial kindergarten reading disparities. This included home literacy environment, parental involvement in school, and parental role strain. However, school and neighborhood conditions contributed more than family characteristics to SES differences in learning rates in reading. The association between school characteristics and reading outcomes suggests that makeup of the student population, as indexed by poverty concentration and number of children with reading deficits in the school, is related to reading outcomes. The findings imply that multiple contexts combine and are associated with young children's reading achievement and growth and help account for the robust relation of SES to reading outcomes.

*Keywords:* socioeconomic status, reading, achievement trajectories

Socioeconomic status (SES) differences in children's reading and educational outcomes are ubiquitous, stubbornly persistent, and well documented (Arnold & Doctoroff, 2003; Duncan, Yeung, Brooks-Gunn, & Smith, 1998; Lee & Burkam, 2002; McLoyd, 1998; Yeung, Linver, & Brooks-Gunn, 2002). Economically disadvantaged children acquire language skills more slowly, exhibit delayed letter recognition and phonological sensitivity, and are at risk for reading difficulties (Whitehurst & Lonigan, 1998). Speculation about the mechanisms through which economic status affects reading achievement often concerns family life, and more recently, contexts like schools and neighborhoods are promising sources of influence. In the present study, we examine the contribution of these multiple settings to SES differences in early reading. This study is guided by ecological and developmental systems theories, in which it is recognized that children's lives unfold within multiple settings and in relationships with multiple others. Each of these settings functions in a dynamic, reciprocal process between the settings and the individual child (Bronfenbrenner, 1979, 1989; Magnusson & Cairns, 1996). Under such perspectives, functioning and development are not merely reflections of children themselves but also of the nature of experiences, resources, and

interactions encountered by children across settings. Functioning and development are also a reflection of how settings interact (see, for example, Early Child Care Research Network, National Institute of Child Health and Human Development [NICHD], 2004). Specifically, these frameworks account for influences of social environment on reading development in terms of (a) the qualities of environments, such as climate, activities, resources, and strains, and (b) the quality of social relations within and across these settings. Through their resources, experiences, and interactions, families, schools, and neighborhoods create auspicious or risky environments for children's reading development.

Social relationships include parent–child, teacher–child, and peer–peer interactions. The nature and quality of interactions with important adults are important to children's academic and social–emotional development (NICHD, 1998, 2000). Maternal warmth and mother–child interaction patterns have been cited as important to children's language outcomes (Hess, Holloway, Dickson, & Price, 1984; Murray & Hornbaker, 1997).

Bronfenbrenner's (1979, 1989) work recognized that systems differ in their proximity to the child, with more distal settings emanating outward from the child. The framework also captures the interrelations of systems. For example, parents' reports of involvement with the school represent the interaction of two settings—the family and the school. Here, we focus on those settings that children have direct contact with, including family, neighborhood, and school characteristics. We recognize that each of these settings may produce unique and cumulative effects on early development. Questions remain about the relative contribution of these contexts to the development of reading and to the relation of SES to early literacy outcomes. Ecological and developmental systems frameworks also suggest ways environments may interact with one another and may thus attenuate or amplify their effects on development. How, for instance, do family, neighborhood, and school contexts combine to channel the effects of SES on reading

development? Because of the relation between early reading outcomes and later academic success, research exploring the contribution of multiple settings to reading outcomes is critical in the effort to deconstruct and identify the processes that give rise to socioeconomic differences in achievement. The theory also recognizes that the relative salience of contexts may shift over time.

Although ecological and developmental system frameworks underscore the need to examine multiple contexts on developmental outcomes (Bronfenbrenner, 1979, 1989; Magnusson & Cairns, 1996), family environment has most often been explored because it is considered to be the principal contributor to differences in early literacy and language development associated with SES. Developmental research is replete with studies examining the relation between child outcomes and family climates of low-SES children. For example, this body of work has demonstrated that children in low-SES households have less exposure to books at home (Evans, 2004; Lee & Burkam, 2002; Vernon-Feagans, Hammer, Miccio, & Manlove, 2002; Whitehurst & Lonigan, 1998) and have parents who are less involved in their schooling (Evans, 2004). These children are less likely to be regularly read to by parents (Federal Interagency Forum on Child and Family Statistics, 2005; Lee & Burkam, 2002; Whitehurst & Lonigan, 1998). Each of these family climate indicators has been cited as a factor underlying disparities in early literacy and language outcomes. With respect to relationship indicators, maternal sensitivity also has been implicated in the association between SES and children's early language abilities (Raviv, Kessenich, & Morrison, 2004). In addition, evidence suggests that differences in the quality of parents' behaviors during joint book reading (Whitehurst & Lonigan, 1998) and in the frequency and the quality of language interaction with parents in the home (Hart & Risley, 1995; National Research Council, 2000) contribute to disparities in early reading-related outcomes.

Only recently has there been an investigation of the influence of more distal settings, including those outside the home, on such reading-related differences. More important, few studies have concurrently examined the effects of multiple contexts on children's learning outcomes (see NICHD, 2004; Weigel, Martin, & Bennett, 2005, for recent exceptions). Exploring the contribution of these additional settings is important because interpreting SES effects as emanating exclusively from the family or the child means that policy and program interventions may focus too narrowly as they attempt to improve the educational outcomes of low-SES children. In addition, by neglecting the interactions of multiple contexts, one risks missing the dynamic and contextual nature of development and its outcomes (Cairns, Elder, & Costello, 1996).

Important differences in classroom, teacher, school, and community resources emerge along socioeconomic lines (Evans, 2004; Kozol, 1991; Lee & Burkam, 2002; Rothstein, 2004), highlighting the fact that socioeconomic disadvantage exposes poor children to multiple risky extrafamilial environments, including low quality child care, poor and distressed schools, and economically depressed neighborhoods. Given the confluence of negative factors associated with socioeconomic disadvantage, research examining the influence of multiple, nested settings may capture more accurately and more fully the influences that shape children's reading and academic growth than do single factor explanations.

Factors that put children at risk for learning and school difficulty, particularly those related to socioeconomic background, are distributed across environments and are not restricted to a single setting (Evans, 2004; Goldenberg, 2002; Leventhal & Brooks-

Gunn, 2000; Pianta & Walsh, 1996). For example, there is a strong association among school quality, classroom quality, and family SES (Entwisle & Alexander, 1993; Pianta, LaParo, Payne, Cox, & Bradley, 2002), particularly in regard to teacher and peer quality, instructional methods, and physical and material resources (Evans, 2004; Kozol, 1991; Lee & Burkam, 2002; Rothstein, 2004). Child and school poverty have also been linked to kindergarten teachers' positive interactions, classroom's instructional climate, and classroom's child-centered climate (Pianta et al., 2002). Differences in classroom quality as early as preschool are connected to early reading-related outcomes (Bryant, Burchinal, Lau, & Sparling, 1994; Dickinson, 2001; NICHD Early Child Care Research Network, 2000). A plethora of studies have assessed the relation of preschool programs, elementary school reading instruction, and peers to reading competence (see NICHD, 2004; Snow, Burns, & Griffin, 1998; Whitehurst & Lonigan, 1998; Xue & Meisels, 2004). This work suggests that classroom environments that are rich in literacy materials, that have teachers with high expectations of students and with adequate preparation to teach reading, that provide opportunities for dialogic reading or for children to be involved in the book reading experience, that provide support and opportunities for writing, and that promote stimulating teacher-child conversations enhance early language and literacy skills. This work also suggests that peers play a role in influencing early reading proficiency, with children in schools with larger concentrations of less skilled, lower SES, and minority peers exhibiting lower gains in reading during the kindergarten year (Xue & Meisels, 2004). However, remarkably few studies have sought to identify the contribution of school characteristics to the relations between SES and children's reading achievement.

Compared with more advantaged peers, economically disadvantaged children are more likely to reside in poorer quality neighborhoods (Evans, 2004; Lee & Burkam, 2002). Although research has highlighted mechanisms by which neighborhoods and communities impact adolescent development, especially behavioral problems, very few of these studies have explored reading outcomes, and research on very young children is rare. What has been done links neighborhood quality, children's verbal ability, IQ scores, and school achievement among young and early school age children (Leventhal & Brooks-Gunn, 2000). Again, however, in this work children's early reading outcomes have not been explicitly examined. These researchers have also not sought to understand the neighborhood characteristics that mediate the relations between socioeconomic background and children's reading achievement.

The current research assessed, among a nationally representative sample of children, the relative contribution of families, schools, and neighborhoods to the relation between SES and children's early reading achievement and growth between kindergarten and third grade. In addition, we sought to identify the predictors that account for this association across contexts and to identify how these relations vary over the first 4 years of school. This research assessed the extent to which the effects of SES on young children's reading development occur through what happens in the school, the neighborhood, and the home. Variables were selected to reflect those that have been previously linked in the literature to reading or academic achievement, with an emphasis on those that may differ across class lines. Accordingly, the present study is designed to answer the following questions:

1. What is the relation between SES and children's reading development from the fall of kindergarten to the spring of the third grade school year?
2. To what extent do resources, experiences, and interactions within family, neighborhood, and school contexts independently and cumulatively explain socioeconomic differences in early reading outcomes and growth? How do these relations vary over the first 4 years of school?

### Method

The data for the present study are from the Early Childhood Longitudinal Study, Kindergarten Class of 1998–1999 (ECLS-K; U.S. Department of Education, National Center for Education Statistics, 2004). The ECLS-K study followed a nationally representative sample of American children from kindergarten through fifth grade, providing a comprehensive picture of children's early family, neighborhood, and school experiences over time. The total sample consists of 21,260 children recruited from 1,277 kindergarten classrooms in public, Catholic, and non-Catholic private schools nationwide. A subsample of 17,401 children was retained in the longitudinal kindergarten to third grade sample. The study design involved multistage probability sampling to achieve a nationally representative sample of children eligible to attend kindergarten in the 1998–1999 school year.

### Instrumentation

During kindergarten, first-, and third-grade school years, the field staff conducted direct child assessments, parental interviews, and observations of the school environment and the community surrounding the school. Teachers and school administrators completed questionnaires during the spring data collection periods in kindergarten, first grade, and third grade. Data for the current analyses come from child, parent, teacher, school administrator, and field staff responses gathered during this time. A description of the items used in the current project follows.

*Child individual reading assessment.* Reading assessments involved a multiple choice or an open-ended format to measure basic skills (including print familiarity, letter recognition, mastery of beginning and ending sounds and rhyming sounds, word recognition), vocabulary (receptive vocabulary), and comprehension (listening comprehension, words in context). Test specifications were based on the 1992 and 1994 National Assessment of Educational Progress framework. The National Assessment of Educational Progress framework was developed to begin at fourth grade; consequently, the framework focuses on skills that are just emerging in early readers. For this reason, early elementary school educators and literacy curriculum specialists helped modify the assessment to be suitable for kindergarten and first grade. Pools of items for the reading assessment were borrowed or adapted, with permission, from published tests, including the Peabody Individual Achievement Test–Revised (Markwardt, 1989), the Peabody Picture Vocabulary Test–Revised (Dunn & Dunn, 1981), the Primary Test of Cognitive Skills (Huttenlocher & Levine, 1990), the Test of Early Reading Ability (Reid, Hresko, & Hammill, 1981), and the Woodcock-Johnson Tests of Achievement–Revised (Woodcock & Bonner, 1989).

Prior to administering the cognitive assessment, the Oral Language Development Scale (Duncan & DeAvila, 1986) was administered to those children identified from their school records (or by their teacher, if no school records were available) as coming from a household whose primary language was not English. This screening test determined whether a child was able to understand and respond to the cognitive assessment items in English. Children who passed the language screener received the full ECLS-K direct assessment battery. Children who did not pass an established cut score on the language screener did not receive the standard reading assessment.

The direct reading assessment consisted of a set of two-stage assessments: a first-stage routing section, followed by several alternative second-stage forms. First, a screening test consisting of 20 items with a broad range of difficulty was used to assign each child to one of three extensive batteries in the second stage of the assessment, in which items varied in difficulty. This was done to reduce testing time and to ensure that children would be required to respond to questions of moderate difficulty. Testing on this second-stage battery continued until the child reached a ceiling of three consecutive items missed. Item response theory (IRT) was used to generate standard scores based on an analysis of the item difficulty and the pattern of right and wrong responses. IRT scale scores allow for longitudinal measurement of achievement gain over time because assessments at each time are measured in a common metric and are therefore comparable across waves. IRT scores from each wave were used in the study's analyses as repeated measures of children's reading outcomes.

*Child variables.* The ECLS-K provides information on child gender, race, age at first assessment, and SES. Field staff identified child gender during the direct child assessment, and this information was subsequently confirmed during the parent interview (1 = female, 0 = male). A child composite for race provided eight categories for race and/or ethnicity. Children of all races are included in the current analyses, but a dichotomous, dummy variable for White children is modeled as a predictor of reading development. Child age reflects the child's age in months at the time of the fall kindergarten assessment. SES is a composite of five pieces of information: father's or male guardian's education, mother's or female guardian's education, father's or male guardian's occupation, mother's or female guardian's occupation, and household income. The index conceptualizes SES in quintiles, with lower scores indicating lower SES. SES is used in the current analyses because it tends to be less volatile than family income and encompasses several dimensions of economic conditions and parental capital beyond income.

*Family variables.* Parent interviews were completed primarily via telephone, and provisions were made to interview parents speaking Spanish, Lakota, Hmong, and Chinese. Parents provided information on child characteristics, family practices and resources, parent well-being, and home learning environment. Parents also reported the number of books the child had in the home (including library books). Data on whether the child had attended a day care center, nursery school, preschool, or prekindergarten program on a regular basis the year before he or she started kindergarten (1 = yes, 0 = no) were used as a measure of whether the child had received center-based care.

Three variables for the current analyses were derived from parents' responses. Home literacy environment is a sum score of

the frequency with which parents engaged in joint book reading with the child, the frequency with which children read (or pretended to read) books outside of school, and the frequency with which household members visited the library with the child. Parents' reports of the frequency of joint reading with the child and the frequency with which the child read (or pretended to read) had the same 4-point scale: 1 = *not at all*, 2 = *once or twice a week*, 3 = *three to six times a week*, and 4 = *everyday*. Library visits with the child within the last month was a dichotomous variable: 1 = yes, 0 = no.

Involvement in child's school is based on the sum of parents' reports of their own or another adult household member's participation in six activities reflecting involvement in the child's school (1 = yes, 0 = no), including attending a parent-teacher conference, attending a parent-teacher association (PTA) meeting, attending an open house, volunteering, participating in fundraising, and attending a school event (kindergarten  $\alpha = .58$ ; first-grade  $\alpha = .61$ ; third-grade  $\alpha = .61$ ). Parental role strain is represented by the average of parents' responses to nine items that assessed degree of difficulty and strain that the respondent experienced in his or her functioning as a parent (1 = *not at all true*, 2 = *somewhat true*, 3 = *mostly true*, 4 = *completely true*). Only four items were asked in the first grade, so an average of kindergarten and third grade data was estimated for first grade (kindergarten  $\alpha = .69$ ; third-grade  $\alpha = .56$ ). Conversely, parental warmth is represented by the average of parents' responses to four items assessing the warmth and closeness experienced in their relationship with the child (1 = *not at all true*, 2 = *somewhat true*, 3 = *mostly true*, 4 = *completely true*). Again, an average of kindergarten and third grade data was estimated for first grade (kindergarten  $\alpha = .54$ ; third-grade  $\alpha = .68$ ).

**Neighborhood variables.** Appraisals of the neighborhood setting were provided by three independent sources: parents, school administrators, and field staff. Parent reports of home neighborhood safety were assessed with a single item in which parents were asked about how safe it was to play in the neighborhood (1 = *not at all safe*, 2 = *somewhat safe*, 3 = *very safe*). Home neighborhood problems is a derived variable created from the sum of parents' responses about five qualities of their neighborhood, including the degree to which the following activities were a problem: garbage or litter in the street, individuals selling or using drugs in the street, burglary or robbery in the area, violent crime in the area, or vacant homes in the area (0 = *no problem*, 1 = *somewhat of a problem*, 2 = *big problem*). The average of the kindergarten and third-grade data was estimated for the first grade (kindergarten  $\alpha = .76$ ; third-grade  $\alpha = .75$ ).

School administrator reports on whether the community the school served was supportive of its goals and activities (1 = *strongly disagree*, 2 = *disagree*, 3 = *neither agree nor disagree*, 4 = *agree*, 5 = *strongly agree*) served as an index of community support for learning. A sum score of the degree to which school administrators viewed eight issues in the community surrounding the school as problems (tension from differences, unkempt areas, substance abuse, gangs, heavy traffic, violent crime, vacant buildings, and crime in the area; 0 = *no problem*, 1 = *somewhat of a problem*, 2 = *big problem*) represents school neighborhood problems (kindergarten  $\alpha = .82$ ; first-grade  $\alpha = .68$ ; third-grade  $\alpha = .76$ ).

Field staff observed and reported the presence of four conditions in the community near the school: litter and trash, graffiti,

boarded-up buildings, and people congregating (1 = *none*, 2 = *a little*, 3 = *some*, 4 = *a lot*). The average across the four items was used as the index of bad conditions near the school. The average of kindergarten and first-grade data was estimated for third grade (kindergarten  $\alpha = .95$ ; first-grade  $\alpha = .93$ ). Finally, the ECLS-K defines school urbanicity on the basis of census tract region: central city; large town, urban fringe; and small town, rural. The current analyses define schools located in the central city as urban; schools in large towns and urban fringe as suburban; and schools in small towns and rural areas as rural. A dichotomous, dummy variable for suburban is modeled as a predictor of reading development.

**School variables.** Classroom teachers completed self-administered questionnaires, providing reports on children's classroom peers, classroom literacy instruction, and teacher background and beliefs. School administrators also completed questionnaires reporting on the percentage of students in the school who were eligible to receive free or reduced price lunch. School poverty status was determined by supplementing this information with school-wide Title I status (at least 50% of the student body is poor), as reported by school administrators. In the case of missing data on the free or reduced price lunch variable, schools implementing school-wide Title I programs were identified as high-poverty schools. Consequently, a dichotomous variable reflecting high- (above 50%) and low-poverty (below 50%) schools was generated. School administrators also indicated whether the child's school was public or private. From this, a dichotomous, dummy variable for private school was generated for the current analyses.

Peers reading below grade is based on teachers' reports of the number of children reading below grade level in the classroom. Teacher experience is the sum of the number of years the teacher had taught at that school and the number of years the teacher had taught at that grade level. Teacher preparation is a variable derived from the sum of five teacher responses concerning their preparation to teach: the number of courses taken on early education, elementary education, and child development; the highest degree earned; and the number of courses taken on teaching reading (kindergarten  $\alpha = .62$ ; first-grade  $\alpha = .61$ ; third-grade  $\alpha = .60$ ).

Teachers reported the frequency of children's participation in several literacy-related activities in the classroom weekly, including working on learning the names of letters, practicing reading aloud and silently, reading a variety of texts, engaging in writing activities, and working on phonics. The number of activities reported varied at each grade level from 10 activities in kindergarten to 14 activities and 6 activities in first and third grades, respectively. Given differences in the scale across waves, items were rescaled to create a common scale: 0 = *never or hardly ever*, 1 = *monthly*, 2 = *weekly*, 3 = *daily or almost daily*. A sum score of these items was calculated across waves and represents literacy instruction (kindergarten  $\alpha = .61$ ; first-grade  $\alpha = .73$ ; third-grade  $\alpha = .69$ ).

### Analytic Sample

Exactly 10,998 of the children sampled in the fall kindergarten frame and followed to the spring third grade frame had positive, nonzero values on the appropriate sampling weight and were retained in the analytic sample. Thus, the present analyses are based on a weighted sample size of 3,842,954 children. Table 1

Table 1  
Percentage Distributions for Selected Characteristics of the Analytic Sample

Population	Total
Child race or ethnicity	
White	58%
Black	16%
Hispanic	19%
Asian	4%
Other	5%
Child sex	
Male	52%
Female	48%
Primary home language	
English	89%
Non-English	12%
Household income	
Below poverty line	21%
At or above poverty line	79%

Note.  $N = 3,842,954$ . Detail sums may not equal totals because of rounding.

presents the demographic characteristics of those whose data are represented in the current analyses.

### Analysis Overview

In the present study, AM (American Institutes of Research & Cohen, 2005; <http://am.air.org/default.asp>), a data analysis package designed to analyze complex sample survey data, was used for estimation of frequency and descriptive information. Because the ECLS-K data are not simple random samples, the analyses took into account the stratification of the survey design, and the study's sampling weights were used when computing frequency and descriptive information as well as tests of statistical significance. Standard errors were adjusted with a Taylor series approach. Use of sampling weights accounts for unequal probabilities of selection and nonresponse, and it also allows inferences from the analyses to be extrapolated to the larger population which the data were meant to represent. For the present analyses, longitudinal child sample weights from the ECLS-K kindergarten to third grade data file were used (C15PW0; this included children with parent interview data across the waves of interest in the analyses).

In addition, because the present study concerned the influence of family, neighborhood, and school variables on children's reading trajectories, growth curve models were estimated with hierarchical linear modeling (HLM) techniques. Growth curve modeling allows for the estimation of achievement trajectories that model change over time in relation to multiple influences. These models support investigation of covariates or predictors that underlie initial reading achievement, growth over time, and achievement outcomes at specific points in time during the period of interest. In the present study, four repeated measures of reading skills are modeled as a developmental trajectory. Specific child demographic characteristics (e.g., gender, SES, race, age) influence children's reading status in the fall of kindergarten and rates of reading growth through third grade. Additional family, neighborhood, and school characteristics help account for variation in children's initial reading, growth through third grade, and performance at specific points

in time beyond what can be accounted for by children's underlying trajectories. The HLM 6 software (Raudenbush, Bryk, & Congdon, 2005) was used to fit the multilevel model. The HLM program allows for the use of sampling weights that are associated with a complex sampling design and permits the estimation of models with random intercepts and slopes. It also permits nonequidistant times of observation, which is relevant in the ECLS-K data.

The data of all models were weighted at the child level in an effort to account for unequal probabilities of selection and nonresponse. The present HLM model has a general three-level nested structure: time at Level 1; child, family, and neighborhood characteristics at Level 2; and school characteristics at Level 3. Initial examination of the smoothed reading trajectories suggested that reading growth was not linear. As exhibited in Figure 1, many children exhibited a spike or growth spurt in reading scores between the spring of kindergarten and the spring of first grade, with slower reading growth exhibited before and after this period. Accordingly, a three-level model with intercept, three linear slope terms (SLOPE K: fall of kindergarten to spring of kindergarten, SLOPE 1: spring of kindergarten to spring of first grade, SLOPE 3: spring of first grade to spring of third grade), and predictors at each of the three levels was modeled. This model provided superior fit to the data as compared with a model including a single linear slope term (i.e., significantly smaller deviance statistic), and it provided greater interpretability. The Level 1 model represents how each child changes over time; the Level 2 model represents variation in growth parameters among children within the same school; the Level 3 model represents variation in growth parameters across schools. The following equations represent each of these models:

$$\text{Level 1: } Y_{tij} = \pi_{0ij} + \pi_{1ij}(\text{SLOPE K}) + \pi_{2ij}(\text{SLOPE 1}) \\ + \pi_{3ij}(\text{SLOPE 3}) \dots + \pi_{pij}(a_{pij}) + \epsilon_{ij},$$

where  $Y_{tij}$  represents child  $i$  in school  $j$ 's reading performance at time  $t$ ;  $\pi_{0ij}$  represents the intercept or the reading performance of child  $i$  in school  $j$  at the initial assessment;  $\pi_{1ij}$  represents the linear slope or the monthly learning rate in reading of child  $i$  in school  $j$  between the fall and the spring of kindergarten;  $\pi_{2ij}$  represents the monthly learning rate in reading of child  $i$  in school  $j$  between the spring of kindergarten and the spring of first grade;  $\pi_{3ij}$  represents the monthly learning rate in reading of child  $i$  in school  $j$  between the spring of first grade and the spring of third grade;  $\pi_{pij}$  represents the strength and the direction of association between predictor variables  $a_{pij}$  and child  $i$  in school  $j$ 's performance at time  $t$ ; and  $\epsilon_{ij}$  represents the time-specific error of child  $i$  in school  $j$  at time  $t$ .

$$\text{Level 2: } \pi_{0ij} = \beta_{00j} \dots + \beta_{0pj}(X_{0pj}) + r_{ij}, \\ \pi_{1ij} = \beta_{10j} \dots + \beta_{1pj}(X_{1pj}) + r_{ij}, \\ \pi_{2ij} = \beta_{20j} \dots + \beta_{2pj}(X_{2pj}) + r_{ij}, \text{ and} \\ \pi_{3ij} = \beta_{30j} \dots + \beta_{3pj}(X_{3pj}) + r_{ij},$$

where  $\beta_{00j}$  represents the mean intercept or the reading performance within school  $j$  at the initial assessment;  $\beta_{10j}$  represents the mean linear slope or the learning rate in reading within school  $j$  between the fall and the spring of kindergarten;  $\beta_{20j}$  represents the linear slope or the learning rate in reading within school  $j$  between the spring of kindergarten and the spring of first grade;  $\beta_{30j}$  represents the linear slope or the learning rate in reading within

Figure 1. Smoothed plots of reading trajectories of a random subsample of children in four schools.

school  $j$  between the spring of first grade and the spring of third grade;  $\beta_{0pj}$  represents the strength and the direction of association between predictor variables  $X_{0pj}$  and child  $i$  in school  $j$ 's reading performance at the initial assessment,  $\pi_{0ij}$ ;  $\beta_{x_{pj}}$  represents the strength and the direction of association between predictor variables  $X_{x_{pj}}$  and child  $i$  in school  $j$ 's linear learning rate in reading during the three periods of interest,  $\pi_{1ij}$ ,  $\pi_{2ij}$ ,  $\pi_{3ij}$ ; and  $r_{ij}$  represents school  $j$ 's deviation from the reading score predicted by the model.

Level 3:  $\beta_{00j} = \gamma_{000} \dots + \gamma_{0p0}(X_{0p0}) + u_{00j}$ ,  
 $\beta_{10j} = \gamma_{100} \dots + \gamma_{1p0}(X_{1p0}) + u_{10j}$ ,  
 $\beta_{20j} = \gamma_{200} \dots + \gamma_{2p0}(X_{2p0}) + u_{20j}$ , and  
 $\beta_{30j} = \gamma_{300} \dots + \gamma_{3p0}(X_{3p0}) + u_{30j}$ ,

where  $\gamma_{000}$  represents the mean intercept or the reading performance at the initial assessment across schools;  $\gamma_{100}$  represents the mean linear slope or the learning rate in reading across schools between the fall and the spring of kindergarten;  $\gamma_{200}$  represents the mean learning rate in reading across schools between the spring of kindergarten and the spring of first grade;  $\gamma_{300}$  represents the mean learning rate in reading across schools between the spring of first grade and the spring of third grade;  $\gamma_{0p0}$  represents the strength and the direction of association between predictor variables  $X_{0p0}$  and mean initial reading performance within school  $j$ ,  $\beta_{00j}$ ;  $\gamma_{x_{p0}}$  represents the strength and the direction of association between predictor variables  $X_{x_{p0}}$  and mean linear learning rate within school  $j$  during the three periods of interest,  $\beta_{10j}$ ,  $\beta_{20j}$ ,  $\beta_{30j}$ ; and  $u_{ij}$  equals overall deviation across schools from the reading score predicted by the model.

All time varying and time invariant covariates were entered into the models per recommendations by Singer and Willett (2003). Time

varying variables include those that may change over time and that are measured at multiple time points, whereas time invariant predictors reflect data that do not change over time. For example, child's gender and race and child's attendance (or nonattendance) at center-based care the year prior to kindergarten are time invariant. Parents in the ECLS-K reported on aspects of the home environment across waves, making these variables time varying. Time-varying predictors predicted time-specific performance, whereas time-invariant predictors predicted the intercept (i.e., initial performance) and slope (i.e., growth over time) parameters. School-level variables, whether time varying or time invariant, predicted the intercept and slope parameters. Because time-varying predictors were entered at Level 2, they also predicted the intercept and slope parameters.

Because HLM cannot fit a four-level model, classroom and teacher characteristics were aggregated and used as covariates at the school level. Neighborhood variables that were associated with school environment were entered as covariates at Level 3. In HLM models, regression coefficients were interpreted as the value of the dependent variable when the contextual predictor and all the other variables in the model were equal to zero or the mean. Accordingly, with the exception of dummy codes, all contextual predictors were grand mean centered at zero to improve interpretability (Raudenbush & Bryk, 2002; Singer & Willet, 2003).

Results

Descriptive Statistics of Analytic Sample

To characterize family, neighborhood, and school characteristics of participating children, we present descriptive information for the analytic sample in kindergarten, first grade, and third grade in Table 1. As might be expected in a representative sample of U.S.

children, White children made up the majority of the sample (56%), and 44% of the children were non-White (16% were reported by parents as Black, 19% were reported as Hispanic; 4% were reported as Asian, and 5% were reported as other). English was the main language in about 9 of 10 homes, and about 1 in 5 families had household incomes that place them below the federal poverty line.

Table 2 presents children's mean reading achievement. Overall, children's reading achievement and reading achievement variability increased over time. Significant socioeconomic differences of 11.1 points were observed between the lowest and the highest quintiles in children's reading. IRT scores were observed in the fall of kindergarten. These differences increased over the first 4 years of schooling. The reading gap between the lowest and the highest quintiles grew by 2.8 points to 13.9 points from the fall to the spring of kindergarten. By the spring of first grade, the gap grew by 9.7 points to 23.6 points. By the end of third grade, it grew another 3.6 points to 27.2 points. This is an overall increase of 16.1 points in the reading score gap between the poorest children and the most affluent children from kindergarten to third grade, though most of the increase occurred in the first grade year. In the following section, we more fully discuss the meaning of these reading point differences.

### Reading Trajectories

Initially, an unconditional model of reading development was estimated to establish the functional form of reading growth in the full sample. Reading achievement was modeled as a linear function of children's initial reading (intercept), growth per month in reading between the fall and the spring of kindergarten (linear slope), monthly reading growth between the spring of kindergarten and the spring of first grade (linear slope), monthly reading growth between the spring of first grade and the spring of third grade (linear slope), and measurement error. The estimated unconditional model is represented by the following equations.

$$\text{Level 1: } \text{READ}_{ij} = \pi_{0ij} + \pi_{1ij}(\text{SLOPE K}) + \pi_{2ij}(\text{SLOPE 1}) \\ + \pi_{3ij}(\text{SLOPE 3}) + \varepsilon_{ij}.$$

$$\text{Level 2: } \pi_{0ij} = \beta_{00j} + r_{ij},$$

$$\pi_{1ij} = \beta_{10j},$$

$$\pi_{2ij} = \beta_{20j}, \text{ and}$$

$$\pi_{3ij} = \beta_{30j}.$$

$$\text{Level 3: } \beta_{00j} = \gamma_{000} + u_{00j},$$

$$\beta_{10j} = \gamma_{100},$$

$$\beta_{20j} = \gamma_{200}, \text{ and}$$

$$\beta_{30j} = \gamma_{300}.$$

Results from the unconditional model suggested that across children, mean initial reading achievement was 25.72 points ( $p < .001$ ), and children gained an average of 1.86 points per month in reading between the fall and the spring of kindergarten ( $p < .001$ ), 2.42 points per month in reading between the spring of kindergarten and the spring of first grade ( $p < .001$ ), and 1.66 points per

month in reading between the spring of first grade and the spring of third grade ( $p < .001$ ). Thus, the rate of children's reading growth differed across the three time periods, with the most rapid acquisition of skills taking place between the spring of kindergarten and the spring of first grade. See Figure 1 for examples of children's smoothed reading trajectories in a random subsample of four schools. The figure illustrates the spike or the heightened reading skill acquisition occurring between the spring of kindergarten and the spring of first grade. In addition, as noted, there was significant variation around intercept and linear slope terms, suggesting that reading trajectories varied across children.

Next, a conditional model was estimated with child demographic characteristics included as predictors of children's initial reading scores and monthly rates of growth in reading across the three time periods.<sup>1</sup>

$$\text{Level 1: } \text{READ}_{ij} = \pi_{0ij} + \pi_{1ij}(\text{SLOPE K}) + \pi_{2ij}(\text{SLOPE 1}) \\ + \pi_{3ij}(\text{SLOPE 3}) + \varepsilon_{ij}.$$

$$\text{Level 2: } \pi_{0ij} = \beta_{00j}(\text{AGE}) + \beta_{01j}(\text{FEMALE}) \\ + \beta_{02j}(\text{WHITE}) + \beta_{03j}(\text{SES}) + r_{ij},$$

$$\pi_{1ij} = \beta_{10j}(\text{AGE}) + \beta_{11j}(\text{FEMALE}) \\ + \beta_{12j}(\text{WHITE}) + \beta_{13j}(\text{SES}),$$

$$\pi_{2ij} = \beta_{20j}(\text{AGE}) + \beta_{21j}(\text{FEMALE}) \\ + \beta_{22j}(\text{WHITE}) + \beta_{23j}(\text{SES}), \text{ and}$$

$$\pi_{3ij} = \beta_{30j}(\text{AGE}) + \beta_{31j}(\text{FEMALE}) \\ + \beta_{32j}(\text{WHITE}) + \beta_{33j}(\text{SES}).$$

$$\text{Level 3: } \beta_{00j} = \gamma_{000} + u_{00j},$$

$$\beta_{01j} = \gamma_{010},$$

$$\beta_{02j} = \gamma_{020},$$

$$\beta_{03j} = \gamma_{030},$$

$$\beta_{10j} = \gamma_{100},$$

$$\beta_{11j} = \gamma_{110},$$

$$\beta_{12j} = \gamma_{120},$$

<sup>1</sup> In the equations, READ = child's reading IRT score; SUPPORT = neighborhood support for the school's goals and activities (as reported by school administrators); AGE = child age; FEMALE = child is female; WHITE = child is White; SES = child's socioeconomic status; PRE K = center-based care prior to kindergarten; HOMELIT = home literacy environment; BOOKS = number of books in the home; INVOLVE = parent involvement in the school; STRAIN = parental role strain; WARMTH = parental warmth; HPROBS = neighborhood problems; HSAFETY = neighborhood safety; BAD = bad conditions near the school; SUBURB = suburban neighborhood; SPROBS = school neighborhood problems; BELOW = number of children reading below grade; INSTRUCT = classroom instruction practices; EXPERIENCE = teacher's number of years experience teaching; PREPARATION = teacher's preparation to teach; POVERTY = school poverty concentration; and PRIVATE = private school.

Note. For Quintile 1,  $n = 765,187$ ; for Quintile 2,  $n = 767,500$ ; for Quintile 3,  $n = 783,296$ ; for Quintile 4,  $n = 758,962$ ; for Quintile 5,  $n = 758,962$ . Total  $N = 3,833,907$ . Numbers in parentheses are standard errors. HLM = hierarchical linear modeling; SES = socioeconomic status; K = kindergarten; 1st = first grade; 3rd = third grade.

$$\beta_{13j} = \gamma_{130},$$

$$\beta_{20j} = \gamma_{200},$$

$$\beta_{21j} = \gamma_{210},$$

$$\beta_{23j} = \gamma_{230},$$

$$\beta_{31j} = \gamma_{310},$$

$$\beta_{32j} = \gamma_{320}, \text{ and}$$

$$\beta_{33j} = \gamma_{330}.$$

According to this piecewise model, children who were older, female, and from higher SES households had higher reading scores at the initial assessment. In addition, female and high-SES children gained reading skills at a faster rate than did their peers between the fall and the spring of kindergarten; White, female, and high-SES children gained reading skills at a faster rate than did other children between the spring of kindergarten and the spring of first grade; and younger, White, and high-SES children gained reading skills at a faster rate between the spring of first grade and the spring of third grade. Of most importance are the parameter estimates representing the effect of family SES on children's initial reading skills and monthly growth during the three periods.

When other child characteristics were controlled for, as SES increased, so did children's reading achievement at the initial assessment in the fall of kindergarten. In fact, children at 1 standard deviation above the mean in SES had reading scores at the initial kindergarten assessment that were 2.24 points higher than children of average SES and 4.48 points higher than children 1 standard deviation below the mean in SES. Given that 1.86 was the average monthly learning rate for the full sample in the kindergarten year, a 2.24-point advantage in initial reading is a head start, for children 1 standard deviation above average in SES, of more than 1 month relative to children of average SES. It is a head start of more than 2 months relative to children 1 standard deviation below mean SES.

Moreover, on the basis of the model, we expected that children who differed by 1 standard deviation in SES would differ by 0.10 points per month in the rate of reading skill acquisition during the kindergarten year, 0.19 points per month between the spring of kindergarten and the spring of first grade, and 0.02 points per month between the spring of first grade and the spring of third grade. Thus, higher SES relates to higher initial achievement in the fall of kindergarten and more rapid reading growth per month across the three periods of interest. The rate of these advantages in

reading growth differs across the three time periods, with the period between the spring of kindergarten and the spring of first grade being that of greatest differentiation by SES (see Table 3 for parameter estimates).

### *Family Characteristics, Reading Achievement, and Growth*

Next, family covariates (home literacy environment, school involvement, parental role strain, number of books in home, and parental warmth) were added to the model to assess the extent to which SES gaps in initial reading and monthly reading growth rates during the three periods of interest could be explained by family characteristics beyond demographic characteristics. This model revealed the effects of family covariates on initial reading scores, monthly reading growth during the three periods, and time-specific reading performance beyond what could be predicted by children's underlying trajectories and demographic characteristics.

 $\beta_{80j} = \gamma_{800}$ .

Comparisons of the SES coefficient on the intercept and the three slope terms from this model with those of the previous demographic model indicated the extent to which mean differences in initial reading scores and learning rates in reading were attributable to family characteristics. In fact, with the addition of family variables, the SES-intercept coefficient was reduced by 16%, though the three slope parameters were not reduced. Thus, characteristics associated with the family context helped account for SES differences in children's initial reading scores, but they did not account for many of the SES differences in the rate at which children gained reading skills during the three periods of interest. Notably, children with richer home literacy environments ( $T = 6.20, p < .001$ , effect size [es] = .07), more books at home ( $T = 2.10, p < .05$ , es = .02), and parents who were less strained in the parenting role ( $T = -3.28, p < .001$ , es = .04) had enhanced time-specific reading performance during the first 4 years of school. On the basis of the model, children who attended center-based care the year prior to kindergarten were expected to have higher initial reading scores ( $T = 4.46, p < .001$ , es = .09), though receipt of such care was not expected to relate to reading growth during any of the three time periods through third grade (see Table 4).

*Neighborhood Characteristics, Reading Achievement, and Growth*

Next, neighborhood covariates were added to the model to allow assessment of the extent to which SES gaps in initial reading and

$$\beta_{80j} = \gamma_{800},$$

$$\beta_{90j} = \gamma_{900}, \text{ and}$$

$$\beta_{100j} = \gamma_{1000}.$$

With the addition of neighborhood variables, the SES-intercept coefficient was reduced by 2%, the slope parameter for the period between the spring of kindergarten and the spring of first grade was reduced by 1%, and the slope parameter for the period between the spring of first grade and the spring of third grade was reduced by 2%. The kindergarten slope parameter was unchanged with the addition of neighborhood covariates. Thus, this model suggested that beyond family and demographic characteristics, neighborhood conditions did not account much for expected differences in children's initial reading achievement in the fall of kindergarten, but they did account for expected differences in rates of children's monthly reading growth as children matured. In addition, schools with poor conditions in the surrounding area ( $T = -2.19$ ,  $p < .05$ ,  $es = .03$ ) had constrained reading growth during the kindergarten year and during the period between the spring of kindergarten and the spring of first grade ( $T = -2.07$ ,  $p < .05$ ,  $es = .02$ ). Community support for learning was related to higher school mean reading scores at the initial kindergarten assessment ( $T = 2.79$ ,  $p < .01$ ,  $es = .1890$ ; see Table 5).

#### *School Characteristics, Reading Achievement, and Growth*

To assess the extent to which SES gaps in initial reading and monthly reading growth rates could be explained by school char-

With the addition of school variables, the SES-intercept coefficient was reduced by less than 1%, and the kindergarten slope parameter was reduced by 4%. The slope parameter for the period between the spring of kindergarten and the spring of first grade was reduced by 13%. Notably, the slope parameter for the period between the spring of first grade and the spring of third grade was

not reduced with school variables added. This suggested that although characteristics associated with the school environment accounted for a small portion of SES gaps in children's initial reading skills, these characteristics accounted for a larger portion of differences in the rates of children's monthly reading growth during the periods of interest, with the largest effect between the spring of kindergarten and the spring of first grade. Notably, in private schools ( $T = 1.92$ ,  $p < .05$ ,  $es = .13$ ), children had higher initial reading scores, and in schools with more children reading below grade level in classrooms ( $T = -2.94$ ,  $p < .01$ ,  $es = .19$ ), children had constrained reading performance at the initial assessment in the fall of kindergarten. In these schools, children evidenced slower average reading growth in the period between the spring of kindergarten and the spring of first grade ( $T = -2.25$ ,  $p < .05$ ,  $es = .03$ ). Children in high poverty schools evidenced slower reading growth between the spring of kindergarten and the spring of first grade ( $T = -2.04$ ,  $p < .05$ ,  $es = .02$ ). There was no evidence that teacher experience, preparation, or classroom literacy instruction influenced initial reading scores or monthly reading growth rates beyond children's anticipated trajectories and demographic and family characteristics (see Table 6). In other work at prekindergarten, elementary, and secondary grade levels, researchers have found no relation (see for example, Early et al., 2006), not even a negative relation (Goldhaber & Brewer, 1997), between teacher background and student achievement.

In sum, these models suggest that the family context best accounts for SES disparities in children's initial reading achievement as they enter school. In addition, schools and neighborhoods best explain SES gaps in children's rates of monthly reading growth, particularly as children mature, whereas the families appear to do less to account for such gaps. The period between the spring of kindergarten and the spring of first grade is the one of the most rapid reading growth for children and the greatest differentiation on demographic, school, and neighborhood characteristics for children. It is important to note, however, that much of the SES gap in

initial reading achievement and in monthly learning rates remains unexplained by the variables included in the model. Table 7 includes random effects for all models.

Discussion

In the present study, we investigated the reading trajectories of children of differing socioeconomic backgrounds, from kindergarten to third grade, using a nationally representative sample. In addition, a special concern was understanding the unique and cumulative role of family, neighborhood, and school contexts in accounting for disparities in reading achievement during this time period. First, when considering family context, the following were all significantly related to reading outcomes: home literacy environment, number of books owned, parent distress, and receipt of center-based care. This result suggests that both family resource and/or investment models (e.g., books in home; Yeung, Linver, & Brooks-Gunn, 2002) and family process models (e.g., parent distress; Yeung et al., 2002) help explain reading outcomes. Of notable importance to reading outcomes are social relationships and processes (e.g., parental role strain).

Next, each of the contexts was associated with SES gaps in initial reading, reading achievement at specific points in time, and/or monthly learning rates. However, resources, experiences, and relationships associated with the family context were most closely associated with reading gaps at the initial kindergarten assessment. The importance of the experiences within the family context for early reading is hardly surprising because most children had experienced little schooling by the first assessment. Specifically, the results suggest that the relation between SES and children's initial reading competence is mediated by home literacy environment, number of books available within the home to the child, parental involvement in the school, parental role strain and warmth, and provision of center-based care prior to kindergarten. This is a useful finding. Although it may be difficult to alter family SES quickly enough to make a difference for young children, interventions can reduce the adverse effects of family mediators. The results of this study underscore the wisdom of programs that direct resources to strengthening family literacy environment, encouraging parental involvement in schools, and reducing parental role strain.

Although family factors were most strongly associated with SES differences in children's reading competence at the initial assessment, they were less associated with differences in gains or lack of progress in children's reading competence up to third grade. Conversely, experiences and resources associated with school and neighborhood conditions were understandably less associated with SES differences in initial reading scores but more closely associated with differences in children's reading skills acquisition rate, particularly during the period of most rapid reading growth—between the spring of kindergarten and the spring of first grade. Thus, there is a reversal in the relative relation of these settings once children enter school, such that qualities of school and community are associated with differences in reading development to a greater extent than is family life. Accordingly, family life can be viewed as being strongly associated with the starting point of children's reading competence, with other ecological settings being more strongly associated with children's reading progress. It is important to note that even in the presence of family characteristics, neighborhood and school characteristics were associated with children's reading performance. This reinforces the need to focus on characteristics and qualities of family life in preschool children and to widen the emphasis to include schools and neighborhoods as children enter school. It is important to note that these findings are consistent with the theoretical framework guiding the study—specifically that the relative salience of contexts may shift over time. As Bronfenbrenner (1989) noted, not only does the child change over time but the systems with which the child interacts change as well. Consequently, the nature of the child's interactions with these systems and their effect on the child may change over time. This is consistent with work by others (Aber, Gephart, Brooks-Gunn, & Connell, 1997) that recognized the differential effects of environmental contexts across developmental epochs.

Few studies, if any, have examined the relation between neighborhood context and reading development of the very young. This study provides preliminary evidence that neighborhood context may in fact be related to children's growth in reading. Specifically, community support for the school and poor physical conditions surrounding the school were associ-

Table 7

ated with children's reading. Future studies should explore in greater detail the nature and the role of neighborhood context on cognitive outcomes and on young children. Exploring the role of various schooling characteristics to reading outcomes and SES disparities in reading is relatively novel. Peers were a critical component of school context associated with children's reading outcomes in the present study. The number of children reading below grade and the presence of low-income peers were consistently associated with initial achievement and growth rates. The present findings, therefore, speak to the importance of grouping and segregation that occurs within schools. Notably, they are consistent with other work (e.g., Coleman, 1966) that suggested that "the social composition of the student body is more highly related to achievement, independent of the student's own social background, than is any school factor" (Coleman, 1966, p. 325). Thus, those designing educational policy to eliminate reading disparities must be aware of the relation of the presence and the concentration of peers with limited skills or fewer economic resources to students' skills and achievement. Teachers' experience, preparation, and classroom literacy instruction were not consistently related to children's reading outcomes beyond their expected trajectories. However, previous findings examining teacher effects have been mixed (Early et al. 2006). With a few notable exceptions, this work has not focused on the reading achievement of very young children. Taken together, the current findings highlight the ecological and systemic nature of development and the fact that resources and experiences across multiple contexts are associated with children's reading development. Moreover, these findings underscore the influence of SES. Consistent with the study's theoretical framework, in which developmental outcomes are a function of dynamic settings and contexts that interact with one another (Bronfenbrenner, 1979, 1989; Magnusson & Cairns, 1996), contexts produce unique and cumulative influences on reading outcomes and disparities.

In addition to describing the relation between family, school, and neighborhood characteristics to SES reading, our analyses also uncovered important phenomena in children's development of early reading competence. The SES-related differences in reading were stark at the initial kindergarten assessment following children's entry to school. Furthermore, the SES gap in reading between the poorest and the most affluent children grew as children progressed through school. The first grade year appears to be a critical time, as the SES gap in reading achievement grew the widest during this period. This may be due to the coming together of phonological processing, rapid accurate decoding, and comprehension by skilled readers during this time while the less skilled readers are still struggling with letter-sound combinations. It is important to note that this period was associated with the greatest differentiation across children on the basis of demographic characteristics and other ecological factors. For example, high-SES children started off as better readers and had more rapid progress than did low-SES children, across the three time periods, with the gap growing the most between the spring of kindergarten and the spring of first grade.

Our analyses also suggest a compounding effect of low quality environments. Children from low-SES homes grow up in home environments poor in literacy experiences. However, their disad-

vantage does not stop there. These children will often enter schools that have a higher proportion of poor children and those with low reading skills (Lee & Burkam, 2002; Phillips & Chin, 2004). Each of these factors is associated with poorer reading outcomes (Xue & Meisels, 2004). Schools may be overwhelmed in trying to serve concentrations of children who require considerable attention and resources. The present analyses support the policy that some schools have adopted of dispersing low-SES children across multiple schools so that there is not a high concentration of low-income children in a single school. Because school attendance areas correspond to neighborhoods and neighborhoods are often economically segregated, this policy often works against the cherished notion of neighborhood schools. As a consequence, stiff resistance to busing has arisen from parents who are unwilling to pay the price of dislocation necessary to implement these programs.

### *Limitations*

Several limitations mark the present study. First, a considerable portion of the SES gap remains unexplained by the models presented in the current analyses. Across models, we were able to account for only 17% of the initial SES gap and up to 16% of the growth rate gaps. Related to this, the selection of covariates for the growth models was not exhaustive of the ECLS-K dataset or of the set of contextual variables that may be related to reading achievement or SES. Certainly, there are other factors that may be linked to reading achievement and SES that were not explored in the analyses presented here. The inability to explain a larger proportion of the SES gap may be a result of the variables selected; that is, other variables may better capture contributing factors to the reading achievement gap. This difficulty also may be due to the limited measurement and the inherent weaknesses of relying on self-report measures of family practices and environmental conditions. Self-reports may be biased and affected by the social desirability of respondents. Others have similarly noted that parents with different educational backgrounds might vary in their ability to provide accurate reports (Dickinson & DeTemple, 1998). In addition, observational techniques or qualitative methods would be especially beneficial in capturing the true nature of children's contexts. For example, important aspects of teacher-child and parent-child interactions and social characteristics of those environments cannot be fully captured by a large-scale dataset like the ECLS-K. The researchers recognize that the advantages associated with using a large, nationally representative sample are tempered by the preclusion of other techniques that offer important insights in the contexts affecting children.

Finally, perhaps a more fruitful analysis of school versus nonschool factors would split gains into seasons and examine school learning versus summer learning. That is, by examining students' reading gains across years, as is done in the present analyses, it is more difficult to truly distinguish school effects from nonschool ones. We also may have underestimated school effects by not partitioning gains by seasons. Analyses by Downey, von Hippel, and Broh (2004) suggested that learning during the summer is more variable than is learning during the school year and that summer experiences are more responsible for the achievement gap. Others (see Rothstein, 2004) have made similar claims that children's summertime experiences

(and afterschool hours) play a role in contributing to disparities in achievement. In similar work, Burkam, Ready, Lee, and LoGerfo (2004) found that social stratification occurs during the summer months, with higher SES children learning more during these periods. However, highly interpretable models in the current analyses mimic children's overall reading and growth experiences, as losses and gains that children experience are cumulative across seasons.

### Strengths

The current study has several strengths. First, the use of a nationally representative sample of children eligible to attend kindergarten in the 1998–1999 school year greatly benefited the present analyses. Unlike previous studies in which convenience samples were used or only poor children were focused on, the present data provide a portrait of children from varying socioeconomic backgrounds and from across the nation. The data are not limited to low-income children living in urban environments, as often occurs in research on the effects of economic disadvantage. Such characteristics add to the external validity of this research. In addition, the current study benefits from the longitudinal nature of the ECLS-K. Rather than traditional cross-sectional designs, which often do not recognize the volatility in family characteristics linked to disadvantage and adversity, the current research may provide a more accurate portrait of the influence of the family environment on reading achievement over time. Moreover, the present study benefits from the comprehensive nature of the ECLS-K data on family and school contexts.

Finally, the current findings provide several implications for policy. To reduce the reading gap, one cannot place emphasis solely on improving experiences, resources, and interactions in any single context. The disadvantages that low-SES children face across contexts are great, and all contexts are associated with disparities in early reading. However, the present models suggest that families and characteristics associated with the home environment are most closely associated with SES gaps in children's reading achievement on entering school. Accordingly, efforts to improve children's home and family experiences, particularly before children arrive at kindergarten, may prove most important in addressing early disparities in reading achievement. For example, it may be beneficial to provide support services to reduce the effects of role strain unduly experienced by low-SES parents before children enter formal schooling. In addition, policies that increase parents' abilities to provide books in the home and to improve the home literacy environment for their children may also benefit young children. Similarly, the provision of prekindergarten childcare may prepare children for the school environment and provide foundational skills.

Researchers and policymakers should take care not to locate the source of reading disparities in children and families without also recognizing the constraints on families or the other contexts that may be at work. Like children themselves, family functioning exists within a larger context (Bronfenbrenner, 1986) so that parent behaviors, practices, and resources are a reflection of the experiences parents face outside of the home. For example, parents' behaviors and beliefs are not independent systems separate from the outside world; instead, they are

shaped by social, political, and economic forces occurring outside of the home. Policies and interventions that fail to recognize such intricacies may not ultimately succeed. Any policy seeking to improve conditions within the family system should seek to produce change in the contexts that families operate within as well.

### Conclusion

The present research suggests that no one solution or effort targeted to any single context will ameliorate the reading achievement gap. Ultimately, those involved in policy and intervention must recognize the ecological, dynamic nature of development and functioning. Children's development is multidetermined and embedded in dynamic, interconnected systems. As Farmer and Farmer (2001) contended, improvement due to interventions is likely to be short-lived if those involved in the interventions fail to understand the interconnection among systems and the ways in which multiple risks constrain developmental trajectories. Thus, as Rothstein (2004) argued, the answer to disparities in reading achievement lies across systems and in the amelioration of the disparate conditions that children and their families experience there.

# Preschool Home Literacy Practices and Children's Literacy Development: A Longitudinal Analysis

Michelle Hood, Elizabeth Conlon, and Glenda Andrews  
Griffith University

In this 3-year longitudinal study, the authors tested and extended M. Sénéchal and J. Le Fevre's (2002) model of the relationships between preschool home literacy practices and children's literacy and language development. Parent-child reading (Home Literacy Environment Questionnaire plus a children's Title Recognition Test) and parental teaching of letters, words, and name writing were assessed 6 months prior to children's school entry. The 143 children (55% male participants; mean age = 5.36 years,  $SD = 0.29$ ) attended Gold Coast, Australia government preschools. Parent-child reading and literacy teaching were only weakly correlated ( $r = .18$ ) and were related to different outcomes consistent with the original model. Age, gender, memory, and nonverbal ability were controlled. Parental teaching was independently related to R. W. Woodcock's (1997) preschool Letter-Word Identification scores ( $R^2_{\text{change}} = 4.58\%$ ,  $p = .008$ ). This relationship then mediated the relationships between parental teaching and Grades 1 and 2 letter-word identification, single-word reading and spelling rates, and phonological awareness (rhyme detection and phonological deletion). Parent-child reading was independently related to Grade 1 vocabulary ( $R^2_{\text{change}} = 5.6\%$ ,  $p = .005$ ). Thus, both home practices are relevant but to different aspects of literacy and language development.

**Keywords:** early home literacy environment, print exposure, reading development, phonological processing, parent-child reading

The secret of it all lies in the parents reading to and with the child.  
—Edmund Burke Huey, *The Psychology and Pedagogy of Reading*

Parents are encouraged to read to their children from an early age to prepare them for literacy acquisition after school entry. The U.S. Commission on Reading argued that reading to children is “the single most important activity in building the knowledge required for eventual success in reading” (Anderson, Hiebert, Scott, & Wilkinson, 1985, p. 23). Thus, the mechanism by which parent-child reading aids the child's reading acquisition is of interest. Reading acquisition is known to be fostered by several preliteracy skills that emerge in the preschool years (e.g., Adams, 1995). These are oral language skills (phonological awareness and vocabulary) and written language skills (especially letter knowledge).

Parent-child reading fosters these preliteracy skills, which provides a mechanism to explain the relationship between parent-child reading and children's own reading. In their meta-analysis, Bus, van IJzendoorn, and Pellegrini (1995) reported moderate effect sizes for the relationships between the frequency of parent-child reading and language skills ( $d = 0.67$ ), emergent literacy (letter knowledge and phonological processing;  $d = 0.58$ ), and reading achievement ( $d = 0.55$ ). Overall, parent-child reading explained around 8% of the variance in early reading skill (Scar-

borough, Dobrich, & Hager, 1991). The effects were larger in younger samples, suggesting that the relationship is stronger around the emergence of reading. Bus et al. also found that the effects of parent-child reading did not differ by socioeconomic status (SES). Even in families with low SES and low literacy level and with few other incentives to become literate, engagement in shared reading had a positive impact on children's language and literacy outcomes.

Sénéchal, Le Fevre, and colleagues examined the association between more formal literacy teaching practices (e.g., direct teaching of letter names and sounds) and these preliteracy skills and subsequent reading (Sénéchal & Le Fevre, 2002; Sénéchal, Le Fevre, Thomas, & Daley, 1998). Sénéchal et al. (1998) found that informal reading and formal teaching were independent factors in the early home environment. Further, formal teaching was more relevant in children's reading acquisition than informal parent-child reading (Sénéchal & Le Fevre, 2002; Sénéchal et al., 1998), yet far fewer parents engage in teaching than in storybook reading with preschool children (Wood, 2002).

Sénéchal and Le Fevre (2002) proposed a causal model of the relationships between preschool parent-child reading and teaching practices, the preliteracy factors related to early reading, and subsequent reading development over the first 3 years of school. The model was based on a theoretical view of learning to read that emphasized the facilitating roles of phonological awareness and letter knowledge in word identification, and of language skills in comprehension processes in reading (e.g., Adams, 1995). Sénéchal and Le Fevre proposed a direct path from frequency of parent-child book reading to receptive language (receptive vocabulary and listening comprehension) skills at the start of first grade, which in turn predicted reading (word reading and passage comprehen-

sion) at the end of third grade. In contrast, there was a direct path from the frequency of parental literacy teaching to emergent literacy skills (consonant–vowel–consonant word decoding, invented spelling, and letter name knowledge) at the start of first grade, which, in turn, was related to reading at the end of first grade. Sénéchal and Le Fevre found no evidence for direct paths from either parental practice to phonological awareness at the start of first grade. Thus, there were distinct pathways from each preschool home literacy practice to different underlying causal components of reading. Parent teaching was relevant in fostering early word identification, whereas parent–child reading was initially relevant in fostering language development. However, by the third grade, once reading involved both word decoding and reading comprehension, these distinct language and emergent literacy paths were both relevant in mature reading.

In the current study, we tested and extended Sénéchal and Le Fevre's (2002) model of the direct and mediated paths between early home literacy practices, children's emergent literacy skills, and subsequent literacy and language skills in a 3-year longitudinal study (preschool to Grade 2) using a different cultural and SES sample (an Australian low- to middle-class sample). We focused on predictors of single-word identification (Woodcock's, 1997, letter–word identification accuracy and a 1-min timed measure of single-word identification rate) rather than comprehension because of the younger age of our sample at the final phase. We also extended the model by examining predictors of spelling development. Both Home Literacy Environment Questionnaire items plus a children's Title Recognition Test (TRT) were used to assess the early home literacy environment. This was intended to capture a wider range of potentially important aspects of the home environment.

Bus et al. (1995) reported that relationships between preliterate and reading outcome measures did not differ depending on whether the home literacy environment was measured using a single question (e.g., the frequency of book reading) or a composite of questionnaire items (e.g., the frequency of book reading, the number of children's books owned, and the frequency of library visits). Sénéchal et al. (1998) argued against the use of questionnaire items on the basis of difficulty estimating the frequency of literacy activities, strong social desirability, and their failure to meet adequate psychometric criteria. The TRT and the Author Recognition Test (ART) are considered more objective measures of parent–child reading that overcome some of these methodological flaws. However, Sénéchal, Le Fevre, Hudson, and Lawson (1996) found that questionnaire items and TRT and ART scores were significantly related, suggesting that they both assess the construct of home literacy environment. TRTs and ARTs consist of real book titles (TRT) and author's names (ART), as well as foils (made-up titles or names). The scoring is based on signal detection theory. The number of foils "recognized" measures response bias, which is used to correct the number of real items recognized. Olson, Wise, Johnson, and Ring (1997) argued that ART and TRT have high error variance because of guessing and the ability to recognize a title or author that has not actually been read. However, Echols, West, Stanovich, and Zehr (1996) argued that many activities that result in recognizing titles or authors that have not been read are themselves indicative of a literate environment (e.g., seeing them in bookstores, libraries, or newspapers).

### Parent–Child Reading and Children's Literacy Development

Greater parent–child reading is consistently associated with more advanced language skills. Between 6.4% and 13% of the variance in language (generally measured as receptive vocabulary) was explained by parent–child reading, measured either as the age that reading first began (Burgess, Hecht, & Lonigan, 2002), a TRT/ART composite (Sénéchal & Le Fevre, 2002; Sénéchal et al., 1998), or a composite of Home Literacy Environment Questionnaire items and TRT (Fritjers, Barron, & Brunello, 2000), with the latter composite accounting for the most variance. These relationships were independent of age, earlier oral skill, phonological awareness, letter knowledge, parental education and personal reading habits, and literacy teaching practices. Meyer, Wardrop, Stahl, and Linn (1994) reported a similar positive relationship between the frequency of kindergarten teachers' reading to children and the children's language. Only Evans, Shaw, and Bell (2000) failed to find a significant relationship.

In contrast, most studies failed to find significant relationships between parent–child reading and children's letter knowledge (Evans et al., 2000; Sénéchal & Le Fevre, 2002; Sénéchal et al., 1998) or phonological awareness (Baker, Fernandez-Fein, Scher, & Williams, 1998; Cunningham & Stanovich, 1993; Evans et al., 2000; Foy & Mann, 2003; Sénéchal & Le Fevre, 2002; Sénéchal et al., 1998) that were independent of age, IQ, oral language, and parental print exposure and education. Significant relationships were found in a couple of studies (Burgess et al., 2002; Fritjers et al., 2000); however, Fritjers et al. (2000) found that phonological awareness perfectly mediated the relationship between parent–child reading and children's letter knowledge.

Studies examining the relationship of parent–child reading and the child's own subsequent reading produced similarly mixed results. The amount of parent–child reading did not differentiate precocious early readers from nonreaders (Stainthorp & Hughes, 2000) or good first grade readers from poor readers (Elbro, Borström, & Petersen, 1998). Estimates of the variance explained in children's Grade 1 word reading by parent–child reading vary from nonsignificant (Sénéchal & Le Fevre, 2002) through 3.2% (Burgess et al., 2002) to 34.9% (Cunningham & Stanovich, 1993). One explanation as to why Cunningham and Stanovich (1993) found that parent–child reading (TRT scores) explained such a large percentage of the variance in Grade 1 reading is that they had a small sample ( $N = 26$ ) that might not have been representative of the general beginner reader population.

Although Sénéchal and Le Fevre (2002) did not find that parent–child reading (TRT/ART scores) predicted Grade 1 reading, they did find that it predicted Grade 3 reading. However, this relationship was perfectly explained by shared variance with Grade 1 receptive language. Thus, the effect of earlier parent–child reading on later reading was indirect.

Cunningham and Stanovich (1993) also examined the relationship between parent–child reading and spelling. They found that TRT scores explained 20%–40% of the variance in spelling, after partialling out variance due to phonological processing. However, Evans et al. (2000) found that both phonological processing and earlier letter knowledge accounted for significant variance in Grade 1 and Grade 2 spelling. Thus, it is possible that earlier letter knowledge mediates any relationship between parent–child read-

ing and children's spelling that is not accounted for by phonological processing.

### Parent Literacy Teaching and Children's Literacy Development

Although limited, the research examining the role of more formal parent teaching practices consistently shows that engaging preschool children in more formal letter-based activities is predictive of children's own emerging literacy skills. Children who were precocious early readers or who had significantly better letter knowledge and emergent word identification skills than their peers had parents who taught them letters and writing skills (Durkin, 1966; Haney & Hill, 2004; Jackson, Donaldson, & Cleland, 1988). Parental teaching accounted for up to 10% of the variance in children's letter knowledge, after controlling for age, cognitive ability, phonological awareness, parent education, and storybook reading (Evans et al., 2000; Sénéchal & Le Fevre, 2002). According to Sénéchal and Le Fevre's (2002) model, the relationship between preschool parent teaching and children's later reading is mediated by this earlier relationship with emergent literacy skills.

Previous studies found mixed results regarding the relationship between parent teaching and language skills. Parent teaching was not directly related to phonological awareness, after controlling for letter knowledge and vocabulary (Foy & Mann, 2003; Sénéchal & Le Fevre, 2002). Haney and Hill (2004) found a trend toward children whose parents taught literacy skills having more advanced vocabulary (composite of receptive and expressive) than those whose parents did not ( $p = .07$ ). When they examined specific teaching practices, they found that teaching letter sounds was related to significantly more advanced vocabulary. However, Sénéchal and Le Fevre (2002) found that teaching did not account for unique variance in receptive language, after variance due to grade level, phonological awareness, emergent literacy, and parent education was accounted for. Evans et al. (2000) also failed to find a significant relationship.

### The Current Study

Sénéchal and Le Fevre's (2002) model formed the theoretical basis for predictions tested in the current study. Studies that examined spelling development (Cunningham & Stanovich, 1993; Evans et al., 2000) were used to extend the model to include predictions about spelling development. The effects of age, gender, memory, and non-verbal ability were controlled. It was expected that parent-child reading (measured as a composite of Home Literacy Environment Questionnaire items and TRT) would be directly related to receptive vocabulary and that this relationship would mediate any relationship between parent-child reading and children's subsequent word reading accuracy and rate. The frequency of parental teaching was expected to be directly related to preschool letter knowledge, and this relationship was expected to mediate any relationship between parental teaching and subsequent development in word reading accuracy and rate. Parent-child reading was expected to be related to spelling rate. We examined the extent to which letter knowledge mediated this relationship. The relationship between parent literacy teaching and spelling development was examined, but no specific predictions were made because of the lack of prior evidence. Consistent with Sénéchal and Le Fevre's model, neither parental reading nor teaching was

expected to be directly related to preschool phonological awareness, independently of letter knowledge and vocabulary. Any relationship between parent-child reading and letter knowledge was expected to be explained by overlapping variance with control measures, such as age, IQ, and vocabulary. Overlapping variance with the control measures and letter knowledge was expected to explain any relationship between parental teaching and vocabulary.

### Method

#### *Participants*

The initial sample comprised 143 preschool children (79 male participants and 64 female participants; mean age = 5.36 years,  $SD = 0.29$ ) who met the selection criteria of no serious developmental or intellectual impairments (parent and preschool teacher report) and English as their main language at home. The language requirement resulted in a largely Caucasian sample, with a few children of Asian or indigenous ethnicity. The three preschools from which the children were drawn were mainly composed of low- to middle-class families. Preschool is a noncompulsory year prior to school entry; however, during the period of this research, 92.6% of children who attended the school in Grade 1 attended preschool there (Education Queensland, 2006). Children attended preschool for 12.5 hr spread over 2.5 days each week. There is no formal instruction in reading or writing; however, children are encouraged to write their names on art works, are regularly read to, and engage in games to promote phonological awareness, such as rhyming and clapping out syllables. Teachers will also assist children who want to write words (e.g., write the word for the child to copy). Formal instruction in reading and writing begins in Grade 1.

In Term 2 of Grade 1 (6–8 months later), 123 of those children (68 male participants, 55 female participants; mean age = 5.95 years,  $SD = 0.30$ ) were available for retesting, and 12 months later in Term 2 of Grade 2, 105 remained available for the third phase of testing (60 male participants, 45 female participants; mean age = 7.02 years,  $SD = 0.29$ ). Thus, the attrition rate from preschool to Grade 2 was 26.6%, which is similar to the attrition rates reported in other longitudinal studies over similar periods (Leseman & de Jong, 1998; Sénéchal & Le Fevre, 2002). There were no significant differences between children who completed the study and those who did not on the early home literacy measures.

#### *Procedure*

School and written informed parental consent were obtained. All testing was conducted individually in a quiet room at the child's school over 6–7 sessions of 5–15 min each. Sessions were on different days over several weeks so fatigue was not a problem. Standardized testing procedures were followed for all commercially available tests. Administration procedures for other tests are described in the *Materials* section.

At the start of the fourth term of preschool, parents completed the Home Literacy Environment Questionnaire, which included a TRT. The children completed the letter-word identification, phonological processing, and memory tasks administered by Michelle Hood. In the Grade 1 and Grade 2 phases, these child measures were repeated, and children also completed the reading and spelling rate measures. Reading and spelling rates were always con-

ducted in separate sessions as they used the same word lists. In the Grade 1 phase, nonverbal ability and receptive vocabulary were also assessed.

### Materials

#### Early Home Literacy Environment

**TRT.** The parent-completed children's TRT included 20 popular age-appropriate children's book titles and 10 foils (see Appendix A). The titles were derived from Angus and Robertson Bookworld's (1999) 100 all-time favorite children's books and previously used TRTs (Cunningham & Stanovich, 1993; Sénéchal et al., 1998). These titles also represented current best sellers. The score was the proportion of real titles checked minus the proportion of foils checked, with negative scores entered as zero. Cronbach's alpha was .74 for the real titles, .64 for the foils, and .76 for the total scale.

**Home Literacy Environment Questionnaire.** Parents responded regarding the frequency of reading to the child, the number of children's books, the frequency of parental teaching of literacy skills, and the frequency of library visits, as well as other nonliteracy activities included as filler items (see Appendix B). Questions were based on those previously used by Sénéchal et al. (1998) and Foy and Mann (2003). The Home Literacy Environment Questionnaire also asked parents about the child's interest in being read to. This was included because a lack of interest by the child may affect the extent to which parents engage in literacy activities with the child. Child interest was significantly correlated with the frequency of parent's reading (Crain-Thoreson & Dale, 1992; Dunning, Mason, & Stewart, 1994; Olofsson & Niedersoe, 1999) and with children's letter knowledge (Fritjers et al., 2000), word and sentence reading (Olofsson & Niedersoe, 1999; Scarborough et al., 1991), and language skills (Payne, Whitehurst, & Angell, 1994; Sénéchal et al., 1998). The questionnaire also requested demographic details (e.g., age, gender, and medical and developmental history).

#### Control Measures

**Memory.** Several authors argued that memory needs to be controlled in predictive studies of reading because of its significant relationship with early reading development (Mann & Liberman, 1984; Molfese, Molfese, & Modgline, 2001; Wagner & Torgesen, 1987). The auditory-verbal short-term memory measure was the Digit Span Forward subtest from the Dyslexia Early Screening Test (Nicolson & Fawcett, 1996), which is suitable for children 4.5–6.42 years of age. Nicolson and Fawcett (1996) reported a 1-week test-retest reliability of .63 for children 5.5–6.5 years of age. We found a 6-month test-retest reliability (preschool to Grade 1) of .60. There were two trials at each digit span from two to nine digits. Testing ceased when two trials at any given span were incorrect. The memory score was the number of correct trials (maximum = 16).

**Nonverbal ability.** This was included as a measure of children's analytic intelligence and was measured with Raven's Colored Progressive Matrices (Raven, Court, & Raven, 1986). The reported Cronbach's alpha for an Australian sample (mean age = 5.5 years) was .80 (Raven et al., 1986). Our obtained alpha was .75.

### Phonological Awareness

There were two measures of phonological awareness. For each measure, *z* scores were formed and summed to give a composite phonological awareness score.

**Rhyme and alliteration detection.** The Rhymes subtest of the Cognitive Profiling System (CoPS; Singleton, Thomas, & Leedale, 1997) was used. CoPS is a computerized early screening test for children age 4.5 years and over. Fawcett, Singleton, and Peer (1998) reported prediction rates for reading risk of over 90% using the CoPS, and acceptable false-negative (12.0%–16.7%) and false-positive (around 2 %) rates. They found a strong correlation ( $r = .52$ ,  $p < .001$ ) between Rhymes performance at 5 years and single-word recognition at 8 years. We found a 6-month test-retest reliability (preschool to Grade 1) of .72 and Cronbach's alphas at each phase of .87–.93.

Participants chose a stimulus word from four choices that sounded like the target word on rhyme trials (eight trials) or that started with the same sound on alliteration trials (eight trials). On each trial, the spoken target and stimulus words were accompanied by pictures of the words on the computer screen, which remained in place until the child responded. This reduced memory demands. At preschool, the children only completed the rhyme trials. At Grades 1 and 2, they completed the alliteration trials if they correctly completed the rhyme trials. Maximum possible scores were 8 at preschool and 16 at Grades 1 and 2.

**Phonological segmentation.** The Phonemic Segmentation subtest of the Dyslexia Early Screening Test (Fawcett & Nicolson, 1996) involves deleting a phonological segment from a word read out by the experimenter (e.g., say *brain* without the /b/ to get *rain*). The deleted segment ranges from a syllable to a single phoneme within a blend, and varies across initial, medial, and final positions within the word. There were 12 trials. Fawcett and Nicolson (1996) reported a 1-week test-retest reliability of .88 for children 6.5–12 years of age. We found a 6-month (preschool to Grade 1) test-retest reliability of .62 and Cronbach's alphas of .57–.61.

### Receptive Vocabulary

The Peabody Picture Vocabulary Test—Revised Form M (Dunn & Dunn, 1981) is a graded test suitable for people 2.5–40 years of age. Participants chose one of four pictures that best illustrated the meaning of a word spoken by the examiner. There were three training items first. Dunn and Dunn (1981) reported split half reliabilities of around .80 for children 5–6.92 years of age. We found a Spearman-Brown-corrected split half reliability of .81.

### Reading

**Letter-word identification.** The Letter-Word Identification subtest of the Woodcock Diagnostic Reading Battery (Woodcock, 1997) is a graded list, beginning with selected letters (upper and lower case) and continuing with words of increasing difficulty. Reported internal consistency was .94 for participants 5–18 years of age (Woodcock, 1997). We found Cronbach's alphas ranging from .83 to .93 across the three phases.

**Reading rate.** This measured word identification fluency. Participants read as many words as possible in 1 min from a list based on the most frequent English words from Dolch's (1936) and

Kucera-Francis’s (1967) sight-word lists (see Appendix C). These words were also contained on the participating school’s sight-word lists for Grades 1–3 as well as the words that the children were expected to be learning. Words were presented in order from highest frequency/easiest in three columns on A–4 pages in size 20 Berlin Sans FB font. The dependent measure was the number correctly identified in 1 min (maximum = 120). Test–retest reliability over the 12 months from Grade 1 to Grade 2 was .79.

Spelling Rate

Children wrote to dictation as many words as possible in 2 min from the list of high frequency words used in the reading rate task (see Appendix C). The experimenter read the word, repeated it in a phrase or sentence, and if the child had not yet finished writing the word, repeated the word again. Immediately when the child finished one word, the next word was read out loud. The dependent measure was the number of correctly spelled words (maximum = 120). Test–retest reliability over the 12 months from Grade 1 to Grade 2 was .71.

Results

Literacy Practices in the Early Home Environment

Appendix B includes the percentages of parents choosing each response option for all items on the Home Literacy Environment Questionnaire. All parents reported reading to their child at least once per week, with 58.4% reading once or more per day. All families owned at least one book per child, with around 75% reporting they owned 50 or fewer. Only 7% of parents reported that their child was not interested or only slightly interested in being read to. A total of 21% reported that they never took the child to the library (although all children visited the school library weekly). Most parents reported that they taught the child the alphabet (81.2%), to write their name (76.3%), and to read (57.4 %) often or very often. Thirteen parents (9.1%) did not report frequency for teaching their child to write their name because they reported that the child could already do that. Six of those parents also did not report the frequency of teaching the alphabet for that same reason. These responses were treated as missing data, and scores were replaced with the median to retain these participants in the sample. These children did not differ significantly on the outcome measures from the children whose parents had reported a frequency of doing these activities at the median for the sample, and they performed significantly better on the outcome measures than those children whose parents reported a frequency for these activities at lower than the median. This supported our replacement of their missing data with the median. The mean score on the TRT was .29 (*SD* = .16; *M*<sub>real</sub> = .35, *M*<sub>foils</sub> = .07). In other words, after correcting for response bias, an average 29.19% of the real book titles were recognized (see Appendix A).

A principal components analysis (varimax rotation) of the Home Literacy Environment Questionnaire items and the TRT produced two factors, labeled Parental Teaching and Parental Reading (see Table 1). Frequency of library visits was excluded as it did not load clearly on either factor. The two factors accounted for 57.82% of the variance in the six remaining items. To form a composite Parental Reading measure, we first standardized reading item

Table 1  
*Principal Components Analysis of Items Measuring Early Home Reading Environment (N = 143)*

Item	Factor loadings	
	Parental teaching	Parental reading
Frequency teach alphabet	.83	.01
Frequency teach write name	.76	.12
Frequency teach reading	.72	.06
No. children’s book per child	.14	.78
Children’s TRT score	–.19	.73
Frequency reading per week	.29	.63
Eigenvalues	2.08	1.39
Percentage of variance	34.64	23.18
Kaiser–Meyer–Olkin measure	0.62	
Bartlett’s test of sphericity	$\chi^2(15) = 126.53, p < .0001$	

*Note.* The minimal factor loading required to be significant at an alpha level of .05 was .50 (Hair, Anderson, Tatham, & Black, 1998). TRT = Title Recognition Test.

scores and then summed them. As the teaching items were all measured on the same response scale, initial standardizing was not required. They were simply summed to form the composite Parental Teaching measure. These two factors were only weakly correlated (3.35% shared variance). Child Reading Interest was significantly correlated with each—more strongly so with Parental Reading than with Parental Teaching (see Table 2). However, it was not significantly correlated with any outcome measures, so it was not included in any further analyses.

Table 2 presents the zero-order correlations, and Table 3 presents the descriptive statistics for the control measures (age, gender, memory, and nonverbal ability), the literacy and language measures, and the home literacy factors. Grade 1 reading and spelling rates were square-root transformed to normalize the positively skewed distributions. These transformed variables were used in the analyses. At preschool, letter–word identification was mainly a measure of letter identification (a score of 13 corresponds to knowing only letters; scores of 14 plus require word identification).

Mediation Analyses

Baron and Kenny’s (1986) approach to testing mediation (see also recommendations of Kenny, Kashy, & Bolger, 1998; Shrout & Bolger, 2002) was used to test the extent to which indirect paths via the potential mediators (phonological awareness, letter identification, and vocabulary) explained the relationship between Parental Reading and Parental Teaching and subsequent literacy and language skills.<sup>1</sup> Figure 1 represents the general mediation model tested. Path c is the direct pathway between the home environment predictors (Parental Reading or Parental Teaching) and the language and literacy criterion measures (vocabulary, reading, and spelling). Paths a and b together represent the mediated or indirect

<sup>1</sup> Vocabulary functioned as an initial outcome measure and then as a mediator between home literacy practices and later outcome measures.

path from the predictor to the criterion measure via the potential mediators (letter identification and vocabulary).

Baron and Kenny (1986) identified three necessary conditions for mediation. First, the predictor must account for significant variation in the hypothesized mediator (see Path a, Figure 1). Hierarchical multiple regression was used to examine this relationship between the home environment factors and the potential mediators. Note that in all of these analyses, variance explained by the control measures was partialled out first. Second, the mediator must account for significant variation in the criterion (see Path b, Figure 1). This was tested by regressing the criterion measure on both the predictor and mediator. In line with the recommendations of Kenny et al. (1998), the second condition is satisfied if the mediator explains a significant independent component of variance in the criterion. The final condition (see Path c', Figure 1) is that when the relationships between the predictor and the mediator (Path a) and between the mediator and the criterion (Path b) are accounted for, a previously significant relationship between the predictor and the criterion (Path c) becomes nonsignificant (complete mediation) or is substantially reduced (partial mediation). Standardized beta coefficients were examined to determine the extent to which the independent contribution of the predictor was reduced. Finally, we applied Sobel's (1982) test<sup>2</sup> (using Preacher & Leonardelli's, 2001, interactive calculation tool) to determine whether this mediated path (Paths a and b) significantly differed from zero.

In all of the subsequent hierarchical regression analyses, control measures were entered at Step 1, prior to home literacy environment predictors, to initially partial out the variance they explained in the specific criterion measure. Control and predictor variables that were not significantly bivariately correlated with that criterion measure (see Table 2) were not included. Results for the control measures are shown in the regression summary tables but are not

detailed further in text. Results with the preschool emergent literacy skills (phonological awareness and letter identification) as criterion measures are presented first, followed by those with receptive vocabulary and then the Grade 1 and Grade 2 outcome measures as the criterion measures.

### *Prediction of Preschool Emergent Literacy Skills by Parental Literacy Practices*

On the basis of Sénéchal and Le Fevre's (2002) model, neither Parental Reading nor Parental Teaching was expected to show a significant direct relationship with Phonological Awareness. Nonsignificant zero-order correlations (see Table 2) confirmed this. Thus, there were no direct paths between the parent practices and early phonological awareness.

Parental Teaching was expected to be directly related to Preschool Letter-Word Identification. The hierarchical regression analyses are summarized in Table 4a. At Step 2, Parental Teaching explained an additional 7.6% of the variance in Preschool Letter-Word Identification (see significant Path c, Figure 1) over that accounted for by the control measures at Step 1. Sénéchal and Le Fevre (2002) found the direct relationship between Parental Teaching and emergent literacy was not explained by Vocabulary or Phonological Awareness. We tested these potential indirect relationships using more formal mediation analysis. Phonological Awareness was not significantly correlated with Parental Teaching (see Table 2) so was not considered further as a mediator (i.e., nonsignificant Path a). However, Vocabulary was significantly correlated with Parental Teaching (see Table 2), and after partialling out variance due to the control measures, Parental Teaching independently explained 5.6% of the variance in Vocabulary,  $F(1, 117) = 8.37, p = .005$  (significant Path a). When Letter-Word Identification was regressed on both Parental Teaching and Vocabulary, Vocabulary independently explained 4.1% of the variance (significant Path b). With this mediated path via Vocabulary accounted for, Parental Teaching still independently explained a significant 4.58% of the variance in Letter-Word Identification. Sobel's test results indicated that the mediated path via Vocabulary did not quite reach significance ( $z = 1.94, p = .051$ ). Thus, consistent with Sénéchal and Le Fevre's model, there were direct paths from both Parental Teaching and Vocabulary to Preschool Letter-Word Identification.

Parental Reading was significantly correlated with Preschool Letter-Word Identification (see Table 2). However, once differences in age, memory, and nonverbal ability were accounted for, this relationship became nonsignificant. Consistent with Sénéchal and Le Fevre's (2002) model, there was no direct path from Parental Reading to Letter-Word Identification.

### *Prediction of Receptive Vocabulary by Parental Literacy Practices*

Sénéchal and Le Fevre's (2002) model predicted that Parental Reading would be related to Vocabulary, independently of rela-

<sup>2</sup> Sobel's formula:  $z \text{ value} = a \times b / \text{SQRT}(b^2 \times s_a^2 + a^2 \times s_b^2)$ , where SQRT = square root,  $a$  = raw regression coefficient ( $B$ ) for Path a,  $s_a$  = standard error of  $a$  ( $SE B$ ),  $b$  = raw regression coefficient for Path b, and  $s_b$  = standard error of  $b$ .

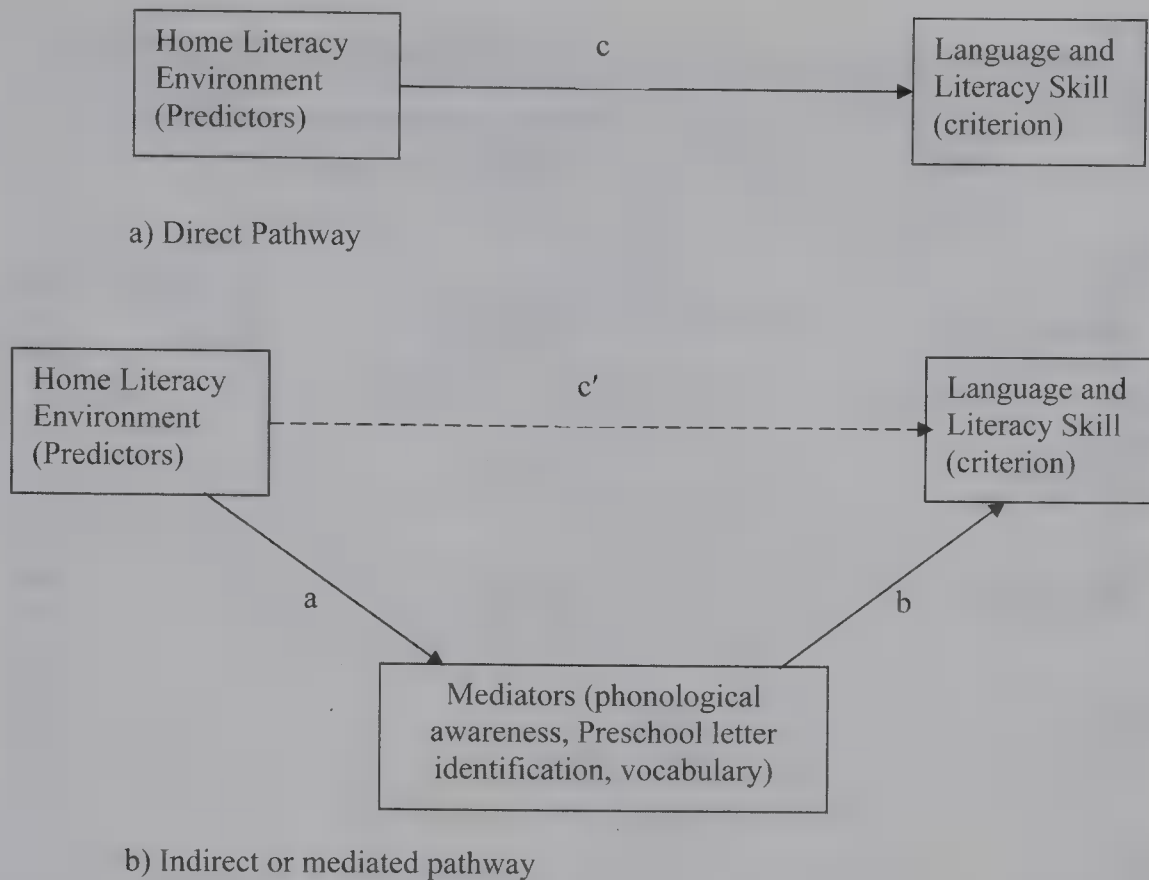

Figure 1. Generic mediation model being tested (on the basis of Baron & Kenny, 1986).

tionships with emergent literacy and phonological awareness. Table 4b summarizes these analyses. At Step 2, Parental Reading independently explained 5.6% of the variance in Vocabulary (significant Path c). Neither Preschool Letter–Word Identification nor Phonological Awareness met Baron and Kenny’s (1986) first condition for a mediator (significant Path a from predictor to mediator), after partialling out variance explained by the control measures (see Table 4a). Thus, there was evidence only for a significant direct path from Parental Reading to Vocabulary that was independent of emergent literacy skills and phonological awareness.

Parental Teaching was also significantly correlated with Vocabulary (see Table 2). With variance due to the control measures explained, Parental Teaching explained 4.5% of the variance in Vocabulary (see Table 4b). Preschool Letter–Word Identification was a potential mediator as it was significantly predicted by Parental Teaching (see Table 4a; Path a). When it was entered in the regression analysis with Parental Teaching, Preschool Letter–Word Identification independently explained 5.6% of the variance in Vocabulary, and Parental Teaching no longer explained a significant percentage of the variance. Thus, there was complete mediation by Letter–Word Identification. This mediated path was significantly different from zero ( $z = 2.13, p = .033$ ). Thus, as predicted by Sénéchal and Le Fevre’s (2002) model, there was only an indirect path from Parental Teaching via Preschool Letter–Word Identification to Vocabulary.

#### *Prediction of Mid-Grade 1 Literacy Outcomes by Parental Literacy Practices*

The criterion measures in this set of mediation analyses were Grade 1 Phonological Awareness, Letter–Word Identifi-

cation, Reading Rate, and Spelling Rate. Parental Reading showed no significant zero-order correlations with any of the Grade 1 outcome measures (see Table 2); thus, no further analyses involving it were conducted. Parental Teaching was significantly correlated with all Grade 1 outcome measures, except Phonological Awareness. Thus, no further analyses predicting Grade 1 Phonological Awareness were conducted, and no paths from parental practices to Grade 1 Phonological Awareness were supported in the model. Table 5 summarizes the separate hierarchical regression analyses conducted for the other Grade 1 criterion measures. Preschool Letter–Word Identification was a potential mediator in all analyses based on significant zero-order correlations with each criterion measure (see Table 2) and significant prediction by Parental Teaching (see Table 4a).

Table 5a summarizes the regressions on Grade 1 Letter–Word Identification. At Step 2, Parental Teaching explained 6.4% of the variance in Grade 1 Letter–Word Identification. When Preschool Letter–Word Identification was also entered at Step 2, it independently explained 37.7% of the variance. Parental Teaching no longer explained a significant percentage of the variance, consistent with complete mediation by Preschool Letter–Word Identification. This mediated path was significant ( $z = 3.32, p = .0009$ ). Thus, there was no direct path from Parental Teaching to Grade 1 Letter–Word Identification—only an indirect path via earlier Letter–Word Identification.

A similar pattern of results was obtained with Grade 1 Reading Rate as the criterion (see Table 5b). At Step 2, Parental Teaching explained a further 7.9% of the variance in Grade 1 Reading Rate. When Preschool Letter–Word was also included in the regression analysis, it independently explained 29.5% of the variance, and the

Table 4

Parent teach	0.88 (0.51)	.14	.09
Preschool letter-word identification	1.06 (0.36)	.27	.004*
	$\Delta R^2 = .056^*$ , $F(1, 117) = 8.55$ , $p = .004$		

Note. The contributions of the control measures beyond Step 1 are not included in any of the summaries in the interests of economy of presentation and because they are not the focus of the analysis

\*  $p < .05$ .

percentage of variance explained by Parental Teaching became nonsignificant. This mediated path was significant ( $z = 3.23$ ,  $p = .001$ ). Thus, any relationship between Parental Teaching and Grade 1 Reading Rate was also completely mediated by Preschool Letter-Word Identification.

Similar results were also obtained in the regression on Grade 1 Spelling Rate (see Table 5c). At Step 2, Parental Teaching explained 5.3% of the variance in Grade 1 Spelling Rate. Preschool Letter-Word Identification independently explained a further 18.9% of the variance in Grade 1 Spelling Rate and reduced the variance explained by Parental Teaching to a nonsignificant level. This mediated path was significant ( $z = 3.00$ ,  $p = .003$ ). Thus, the only path supported was a mediated path from Parental Teaching via Preschool Letter-Word Identification to Grade 1 Spelling.

### *Prediction of Grade 2 Phonological Awareness, Reading, and Spelling*

Parental Reading showed no significant zero-order correlations with any Grade 2 outcome measures (see Table 2) and was not included in further analyses. However, there were significant correlations between Parental Teaching and all Grade 2 criterion measures. Preschool Letter-Word Identification was a potential mediator of these relationships.

Prediction of Grade 2 Phonological Awareness is detailed in Table 6a. At Step 2, Parental Teaching explained an additional 7.4% of the variance in Grade 2 Phonological Awareness. When both Parental Teaching and Preschool Letter-Word Identification were entered at Step 2, Preschool Letter Word Identification explained 15.29% of the variance, and the contribution of Parental

<sup>a</sup> Male = 1, Female = 0.

\*  $p < .05$ .

Teaching became nonsignificant. This mediated path was significant ( $z = 2.90$ ,  $p = .004$ ). Grade 1 Phonological Awareness was then added at Step 3. With it added, the mediated path remained significant, explaining 2.69% of the variance in Grade 2 Phonological Awareness. Grade 1 Phonological Awareness independently explained a further 11.7% of the variance. Thus, an indirect path from Parental Teaching via Preschool Letter-Word Identification to Grade 2 Phonological Awareness, which was independent of earlier phonological awareness, was supported in the model.

With Grade 2 Letter-Word Identification as the criterion measure, Parental Teaching explained an additional 4.63% of

the variance at Step 2 (see Table 6b). With both Preschool Letter-Word Identification and Parental Teaching entered at Step 2, Letter-Word Identification independently explained 17.06% of the variance, but the independent contribution of Parental Teaching became nonsignificant. When Grade 1 Letter-Word Identification was added at Step 3, it independently explained 37.5% of the variance, and Preschool Letter-Word Identification no longer explained a significant independent percentage of the variance. Thus, any variance in Grade 2 Letter-Word Identification explained by Parental Teaching overlapped with that already accounted for by the mediated path from Preschool to Grade 1 Letter-Word Identification. There

Parent teach	0.97 (0.34)	.26	.006*
$\Delta R^2 = .064^*$ , $F(1, 101) = 7.95$ , $p = .006$			
Step 2.			
Parent teach	0.61 (0.34)	.16	.072
Preschool letter-word identification	0.91 (0.24)	.36	<.0001*
$\Delta R^2 = .169^*$ , $F(2, 100) = 11.94$ , $p < .0001$			
Step 3.			
Parent teach	0.29 (0.28)	.08	.303
Preschool letter-word identification	0.20 (0.22)	.08	.376
Grade 1 spell rate	4.20 (0.60)	.62	<.0001*
$\Delta R^2 = .237^*$ , $F(1, 99) = 49.79$ , $p < .0001$			

\*  $p < .05$ .

was a further direct path from Grade 1 to Grade 2 Letter-Word Identification.

Results were similar for the other criterion measures. At Step 2, Parental Teaching explained an additional 8.58% of the variance in Grade 2 Reading Rate (see Table 6c). Adding Preschool Letter-Word Identification at Step 2 independently explained a further 18.75% of the variance, and the independent contribution of Parental Teaching became nonsignificant. At Step 3, Grade 1 Reading Rate independently explained a further 39.69% to the variance and reduced the contribution of Preschool Letter-Word Identification to nonsignificance. Thus, a mediated path from Parental Teaching via Preschool Letter-Word Identification to Grade 1 Reading Rate and from there a direct path to Grade 2 Reading Rate was supported.

At Step 2, Parental Teaching independently explained 6.4% of the variance in Grade 2 Spelling Rate (see Table 6d). Preschool Letter-Word Identification completely mediated this relationship and independently explained a further 10.5% of the variance. However, when Grade 1 Spelling Rate was also added, the contribution of Preschool Letter-Word Identification became nonsignificant. Grade 1 Spelling Rate independently explained 23.72% of the variance in Grade 2 Spelling Rate. Thus, there was only a mediated path from Parental Teaching via Preschool Letter-Word Identification to Grade 1 Spelling Rate, which was then directly related to Grade 2 Spelling Rate.

### Discussion

We examined the extent to which preschool home literacy teaching and reading practices account for significant variance in emergent literacy skills (phonological awareness and letter identification) at preschool and in language and literacy skills in Grade 1 and Grade 2. On the basis of results of previous studies and in particular the model proposed by Sénéchal and Le Fevre (2002), we examined the direct and mediated relationships between these

home literacy factors and the outcome measures, when variance shared with age, gender, nonverbal ability, and memory was controlled. The results indicate that parent-child reading and parent literacy teaching practices were only weakly related factors in the early home environment and that they showed different relationships to language and literacy outcomes. The model in Figure 2 summarizes our overall findings. This not only confirms the generalizability of Sénéchal and Le Fevre's model to an Australian sample drawn from schools servicing low- to middle-SES families but extends it to include both accuracy and rate of word reading as well as spelling rate.

The home environments of the children prior to school entry included a number of literacy activities. In general, the findings were consistent with previous studies that used samples from a variety of SES backgrounds in North America, the Netherlands, and England. Thus, the type of literacy practices that parents use with preschool children generalize across nationalities, languages, and SES boundaries. The number of children's books owned was comparable with previous studies (Foy & Mann, 2003; Sénéchal et al., 1998). The frequency with which the parents read to their children during preschool (approximately 60% reading daily) was also consistent with previous studies (Sénéchal et al., 1998; Wood, 2002). However, more parents in our study than in previous studies (Haney, & Hill, 2004; Wood, 2002) reported engaging in letter-based teaching activities. This difference may be due to our sample being older and closer to the start of formal schooling (mean age = 5.36 years compared with 4 years in Wood's, 2002, study and 3-5 years in Haney & Hill's, 2004, study). As children near formal schooling, parents may be more likely to increase the frequency of letter teaching practices. There was an indication of this in Sénéchal et al.'s (1998) study, with the average frequency of parental teaching being *sometimes* for kindergarten children and *often* for the children beginning Grade 1. Furthermore, in their conclusions to the Baltimore

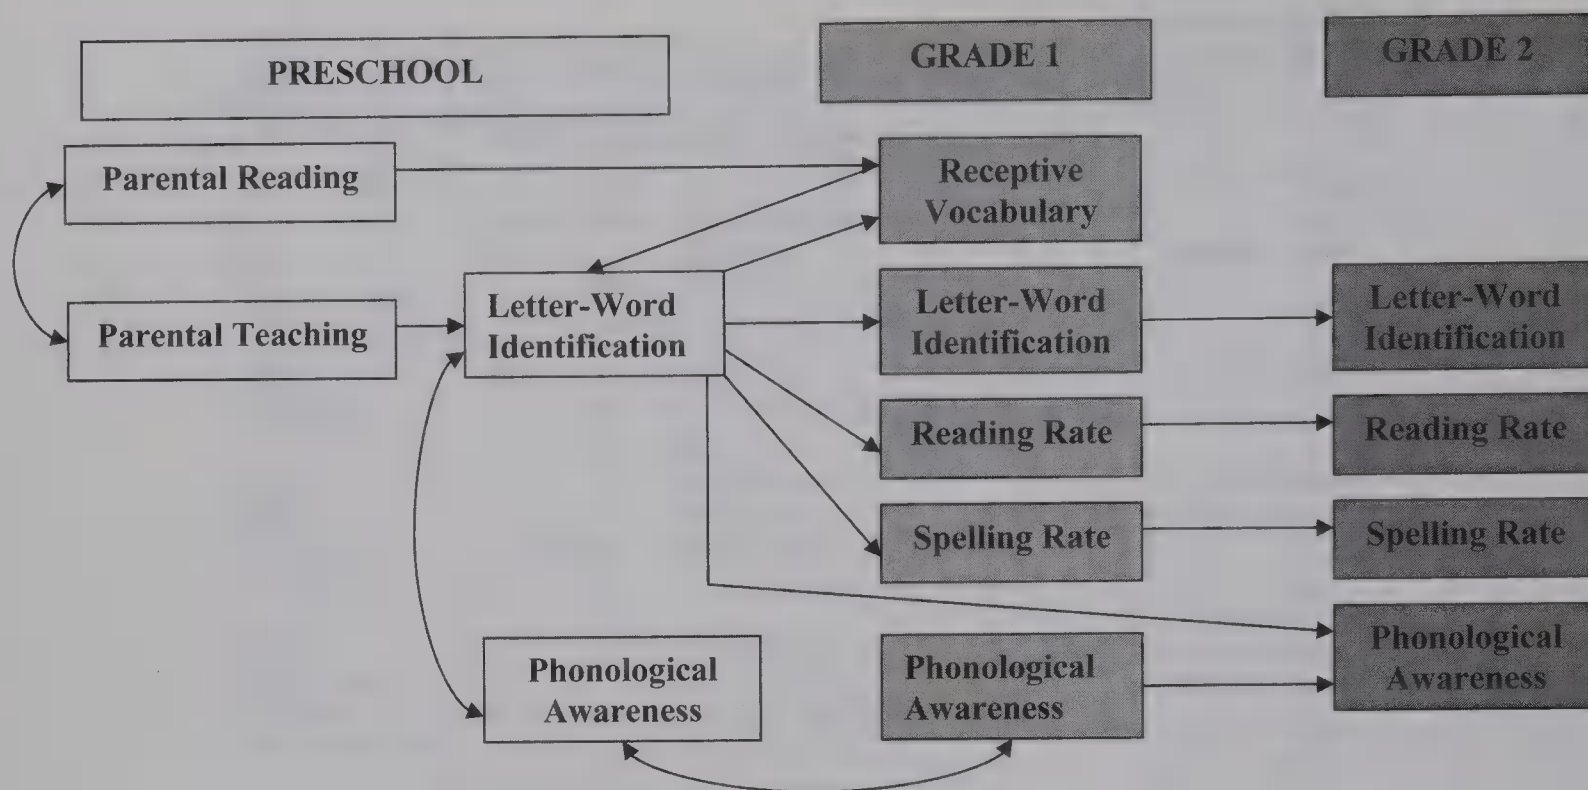

Figure 2. Model of the relationships between early home reading and teaching practices and child literacy and language outcomes, after the effects of age, gender, memory, and nonverbal ability were partialled out. Curved arrows represent paths from Sénéchal and Le Fevre's (2002) model that we did not rigorously test because of the lack of relationships with the focal parent factors but for which we found significant zero-order correlations.

Early Childhood Project, Serpell, Baker, and Sonnenschein (2005) stated that literacy goals were not of paramount importance to parents of prekindergarten-age children.

Consistent with Sénéchal and Le Fevre's (2002; Sénéchal et al., 1998) findings, parental reading and teaching practices loaded on different factors, with little shared variance. Unlike Sénéchal, Le Fevre, and colleagues, we used both Home Literacy Environment Questionnaire items regarding reading frequency and a TRT as our parent-child reading factor. Fritjers et al. (2000) argued that more variance can be accounted for when multiple items are used. Indeed, in post hoc analyses, we found that the correlation between our composite measure and vocabulary (the only significant independent relationship found) was stronger ( $r = .30, p = .001$ ) than was that with the TRT measure alone ( $r = .18, p = .044$ ).

We found a clear difference in the relationships between Parental Reading and Parental Teaching and the literacy and language measures. Consistent with Sénéchal and Le Fevre's (2002) model and other previous studies (e.g., Echols et al., 1996; Nagy & Anderson, 1984; Nagy, Herman, & Anderson, 1985; Scarborough et al., 1991; Sénéchal et al., 1998), parent-child reading was directly related to receptive vocabulary, independently of age, memory, nonverbal ability, and emergent literacy skills. In contrast, Parental Teaching was not directly related to Vocabulary but was directly related to Preschool Letter-Word Identification. The relationship between Parental Teaching and Letter-Word Identification then mediated the relationships between Parental Teaching and all later measures.

We failed to find significant correlations between parent-child reading and children's later reading. Sénéchal and Le Fevre (2002) found that preschool storybook reading was related to Grade 3

reading, but their measure was quite different to ours, incorporating reading vocabulary and reading comprehension. Thus, their result may be largely influenced by a relationship between storybook exposure and reading comprehension that emerges later—an outcome that Leseman and de Jong (1998; de Jong & Leseman, 2001) also found. Furthermore, all of those studies found that relationship was fully mediated by early receptive language skills. Thus, parent-child reading was not directly related to later reading ability.

Studies with older children found that TRT/ART measures were generally related to reading, spelling, phonological processing, and orthographic processing, as well as to vocabulary (Byrne, Fielding-Barnsley, Ashley, & Larsen, 1997; Cipielewski & Stanovich, 1992; Cunningham & Stanovich, 1990, 1991; Echols et al., 1996; McBride-Chang, Manis, Seidenberg, Custodio, & Doi, 1993; Stanovich & West, 1989). It is possible that these different results between samples of beginner and more experienced readers arise because these recognition tests are quite different measures when used with prereaders than when used with older independent readers. With prereaders, parents complete the TRT/ART, so it is a measure of the parent's exposure to children's literature and, thereby, a measure of parental reading to the child. For the pre-reading child, being read to is largely an oral language experience and so the TRT/ART is related to language development. For an older child who is reading independently and completes the TRT themselves, it is a measure of their own independent print exposure. Greater print exposure results in more experience in word and sentence decoding and recognition and in reading comprehension, as well as ongoing exposure to new vocabulary. This explains the relationships between TRT/ART and a range of reading, spelling,

and language measures in older samples that are not found when parent-completed TRT/ART measures are used in younger samples.

Consistent with Sénéchal and Le Fevre's (2002) model and other studies (Baker et al., 1998; Cunningham & Stanovich, 1993; Evans et al., 2000; Sénéchal et al., 1998), neither parent-child reading nor literacy teaching was significantly related to phonological awareness at Preschool or Grade 1. Parental teaching was significantly related to phonological awareness at Grade 2; however, this was completely explained by differences in letter identification at preschool. Foy and Mann (2003) found a weak direct relationship between TRT and rhyme, but not phoneme, awareness. Our composite measure of phonological awareness included both rhyme and phoneme awareness, as did the measure used by Sénéchal, Le Fevre, and colleagues (Sénéchal & Le Fevre, 2002; Sénéchal et al., 1998). This might explain why our studies did not find this relationship. This explanation is further supported by our post hoc analyses that revealed a significant weak correlation ( $r = .19$ ) between our composite reading factor and rhyme awareness at preschool (but not at later phases) that was independent of age, memory, and nonverbal ability. The correlation with phonological segmentation (more focused on phoneme awareness) was not significant.

One reason why stronger relationships with phonological awareness are not found in these studies may also be the parental practices asked about. Our reading questions, like the other studies (Foy & Mann, 2003; Sénéchal & Le Fevre, 2002), focused on story book reading, and our teaching questions focused on letter- or word-based teaching—practices likely to foster vocabulary and letter knowledge, respectively, rather than phonological awareness. Previous studies found that the frequency of rhyming activities (Fernandez-Fein & Baker, 1997) and of reading alphabet books (Murray, Stahl, & Ivey, 1996) was related to children's phonological awareness. Future research needs to canvass a wider range of home literacy practices (including rhyming and letter sound teaching) to clarify whether parental literacy practices can foster phonological awareness.

In contrast to our results with parent-child reading, parental teaching was related to preschool letter identification, independently of associations with age, memory, nonverbal ability, and vocabulary. This relationship then completely mediated the relationships between parental teaching and later word reading and spelling measures, as well as phonological awareness. Theoretical models and empirical evidence supports letter knowledge around school entry as an important predictor of early reading acquisition (Adams, 1995; Scarborough, 1998). Our results show that it is via their relationship with this emergent literacy skill, rather than with early phonological awareness, that home teaching practices (at least as we measured them) are related to Grade 1 word reading and spelling, and that is then directly related to Grade 2 word reading and spelling. The pattern of relationships with spelling was very similar to that with word reading, and the pattern of relationships was similar regardless of whether the outcome was word reading accuracy or rate. Thus, our results confirm that parental teaching practices are significant predictors of emergent literacy skills at the beginning of formal education but that they only have an indirect effect on literacy skills after formal schooling commences. de Jong and Leseman (2001) also found that measures of the early home environment were related to literacy skills at the

start of formal schooling but did not show direct relationships to these skills within 1 year of formal schooling.

We also included a measure of the child's interest in being read to (parent report). Previous studies found that this was related to the frequency of parent-child reading (Crain-Thoreson & Dale, 1992; Olofsson & Niedersoe, 1999) and loaded on the same factor (Dunning et al., 1994). We found child interest was related to both parent-child reading and teaching, having a slightly stronger relationship with parent-child reading. However, unlike previous studies (Fritjers et al., 2000; Olofsson & Niedersoe, 1999; Payne et al., 1994; Scarborough et al., 1991; Sénéchal et al., 1998), we found no relationship between child interest and any of the outcome measures. This might be explained by characteristics of our measure. We had only a single item based on parent report, which was highly skewed (most parents reported their child was very interested).

Our results, combined with previous studies, confirm that similar early home literacy practices are engaged in across a range of SES and cultural backgrounds, and show similar relationships with children's language and literacy outcomes. This is consistent with Bus et al.'s (1995) conclusion that the effects of home literacy practices did not differ among SES; even in low SES families, more shared reading had a positive impact on children's outcomes. However, in the Baltimore Early Childhood Project, Serpell et al. (2005) found that home literacy practices did differ with SES. Therefore, it is a limitation of our study that we did not directly measure SES and compare practices and relationships across SES groups. Notwithstanding that, a major conclusion of the Baltimore Early Childhood Project was that parental practices and beliefs (what they called, the intimate culture) were more important to literacy development than SES. After controlling for parent education, an indicator of SES, Sénéchal and Le Fevre (2002) also found that parent literacy practices were independently related to the language and literacy outcome measures. Burgess (2005) found that a complex network of environmental, educational, and attitudinal variables—not just SES—explained the quality of early home literacy environments provided by teen mothers.

This study adds to the evidence that preschool literacy teaching practices in the home environment are more important than storybook reading in fostering emergent literacy skills and that parents should be encouraged to do more than just read to their children. However, further work is needed to determine the factors that predict parents choosing to engage in more formal literacy teaching over, or in addition to, storybook reading. It may be important for future research to consider this within a developmental context. For example, what specific teaching practices are important for fostering emergent literacy skills at different developmental points prior to school entry, and to what extent are parents sensitive to their child's developing literacy skills, adapting their literacy practices accordingly? Longitudinal studies that begin at an earlier age and that examine a broader range of home literacy practices, ideally with both self-report and observational measures, are needed to clarify developmental changes in the type of practices used and in their relationships to different literacy and language outcomes. We only examined practices in the few months prior to school entry and only examined storybook reading and letter-based teaching activities. Nursery rhymes and other sound games may be more important practices with younger children (e.g., see Bradley

& Bryant, 1983) and may be more strongly related to the other important preliterate skill of phonological awareness.

Parent factors may influence the type of practices engaged in and their effectiveness in promoting children's literacy development. In the current study, we did not determine which parent completed the Home Literacy Environment Questionnaire. It would be of interest in future studies to determine whether fathers and mothers differ in the practices they engage in. Differences in parents' own literacy skills and interest levels may also contribute to differences in the practices engaged in and their effects on child outcomes.

Another factor that may be important, but which is also not addressed in the current study, is the emotional quality of the parent-child literacy interactions (Baker et al., 1998; de Jong & Leseman, 2001; Serpell et al., 2005). de Jong and Leseman (2001) found that the social-emotional quality during parent-child reading was related to vocabulary development and, thereby, to later reading comprehension. Serpell et al. (2005) found that the social-emotional quality was also related to the child's reading motivation and, thereby, to reading frequency once at school. More frequent reading by the child once at school was related to better reading achievement. However, little is currently known about the way social-emotional quality during parental literacy teaching practices is related to children's literacy outcomes. It is possible that unless the parent feels comfortable and competent engaging the child in literacy teaching practices, the social-emotional quality will be less than optimal, and the outcomes may be less satisfactory. This is yet another way in which parents' own literacy skill and interest levels might be related to children's literacy outcomes.

In conclusion, despite our finding that home literacy teaching practices are more important to subsequent literacy development than parent-child reading, reading should not be dismissed in favor of formal teaching practices. Parent-child reading is related to greater vocabulary development, which others have shown is an important predictor of later reading comprehension. Depending on a positive socioemotional context, parent-child reading is also important in fostering the child's own motivation, which has important long-term consequences for their reading as well. Although the direct relationships of parental teaching practices are more obvious earlier in literacy emergence, the indirect relationships of early parent reading may not become apparent until the focus of reading changes from basic word decoding to comprehension, around Grade 3. Thus, parents should be encouraged to engage in both reading and teaching activities to optimize a range of important literacy-related outcomes after school entry.

# Repeated Reading Intervention: Outcomes and Interactions With Readers' Skills and Classroom Instruction

Patricia F. Vadasy and Elizabeth A. Sanders  
Washington Research Institute

This study examined effects of a repeated reading intervention, *Quick Reads*, with incidental word-level scaffolding instruction. Second- and third-grade students with passage-reading fluency performance between the 10th and 60th percentiles were randomly assigned to dyads, which were in turn randomly assigned to treatment (paired tutoring,  $n = 82$ ) or control (no tutoring,  $n = 80$ ) conditions. Paraeducators tutored dyads for 30 min per day, 4 days per week, for 15 weeks (November–March). At midintervention, most teachers with students in the study were formally observed during their literacy blocks. Multilevel modeling was used to test for direct treatment effects on pretest–posttest gains as well as to test for unique treatment effects after classroom oral text reading time, 2 pretests, and corresponding interactions were accounted for. Model results revealed both direct and unique treatment effects on gains in word reading and fluency. Moreover, complex interactions between group, oral text reading time, and pretests were also detected, suggesting that pretest skills should be taken into account when considering repeated reading instruction for 2nd and 3rd graders with low to average passage-reading fluency.

**Keywords:** multilevel modeling, fluency, repeated reading, verbal efficiency, paraeducators

Repeated reading is a widely used practice (Meyer & Felton, 1999; Samuels, 1979) to increase reading fluency (National Reading Panel, 2000); yet, despite its use and acceptance, it is not an entirely standardized procedure. For example, there is no consensus regarding how long and intense it must be to be effective (Chard, Vaughn, & Tyler, 2002), and most research on repeated reading has been conducted on relatively short interventions (Wolf & Katzir-Cohen, 2001). Repeated reading interventions may require students to reread the same texts or different texts, and again, it is not clear which of these methods is more beneficial (Kuhn & Stahl, 2003). When repeated reading is implemented, it may be assisted by an adult reader or teacher, and it is unclear whether the most effective method depends upon the student's skills and developmental needs (National Reading Panel, 2000). Finally, the type of text that is most beneficial to use in a repeated reading intervention is not well specified (Kuhn & Stahl, 2003). There are equivocal findings whether independent or instructional-level text

is associated with greater fluency gains (Kuhn & Stahl, 2003). Less is understood about the role of text characteristics that, as Menon and Hiebert (2005) suggested, may mediate instructional and fluency gains. These text characteristics include total number of words, word repetitions, and word frequency (i.e., the likelihood that the words reread will be encountered and reinforced in other grade-level texts or instructional content). The number of word repetitions or exposures during reading instruction may contribute to the growth of word recognition skills (Juel & Roper-Schneider, 1985).

Researchers' increased understanding of the subtypes of dysfluent students (Berninger, Abbott, Billingsley, & Nagy, 2001) and stages of fluency development raises questions about the grade levels and developmental stages when repeated reading may be most effective for fluency as well as comprehension. The importance of specifying treatment effects for particular stages of fluency development is underscored by the work of Schwanenflugel et al. (2006). In support of their simple reading fluency model they found that for children in Grades 1 to 3, a single reading fluency factor that included word reading accuracy and efficiency skills and object naming was related to comprehension. The National Reading Panel (2000) summarized limitations and directions for future research on fluency, including the need for explicit treatment descriptions of amount of rereading, type of feedback, and difficulty level of materials. The present study attempts to specify more fully the features of a supplemental fluency intervention for students with a range of emerging fluency performance. We also examine features of students' classroom instruction that may influence reading skill growth and interact with fluency treatment.

Fluent reading reflects the development and consolidation of subskills that permit the student to allocate attention to constructing a meaning of the text (LaBerge & Samuels, 1974). According to Perfetti's (1985, 1992; Perfetti & McCutchen, 1987) verbal efficiency theory, the efficiency of phonological, orthographic, and

semantic processes underlies word recognition and retrieval, and differences in these lexical retrieval processes influence comprehension. Slow and inefficient word identification creates a bottleneck that diverts cognitive resources required for comprehension. Verbal efficiency theory predicts that efficiency in word and text reading accuracy and speed will produce improved comprehension. The research on training in verbal efficiency, however, is mixed. Two types of training have been used to develop fluency: training to recognize single words and practice in reading connected text (repeated reading). Fleisher, Jenkins, and Pany (1979) trained students to read words in isolation and in word phrases, and although both types of training increased decoding accuracy and speed for single words, training did not improve comprehension. Others have also failed to show transfer to reading comprehension through training in single-word reading (Yuill & Oakhill, 1988). In a replication of the Fleisher et al. study, Tan and Nicholson (1997) used training in single-word reading to produce gains in comprehension. Others have reported training in single words or connected text generalized to comprehension (Levy, Abello, & Lysynchuk, 1997; O'Shea, Sindelar, & O'Shea, 1985; Samuels, Dahl, & Archwamety, 1974), with reports of mixed effects (Roth & Beck, 1987). Findings on verbal efficiency training are difficult to interpret due to differences in student age and developmental level, training focus, and comprehension tasks.

For practical purposes we define fluency as "rate and accuracy in oral reading" (Torgesen, Rashotte, & Alexander, 2001). However, our assessments reflect an emerging understanding of fluency that encompasses subcomponent skills and executive coordination processes (Berninger et al., 2001) as well as the developmental nature of fluency (Kame'enui, Simmons, Good, & Harn, 2001). Of particular interest in this study of second- and third-grade students was word reading efficiency or automaticity, which is also represented in Schwanenflugel et al.'s (2006) simple reading fluency model of emergent fluency development. Both the more classic and contemporary theories of fluency predict that word recognition and retrieval skills explain individual variance in children's fluency rates in reading connected text.

Several published reviews of fluency instruction have summarized the theory and nature of fluency interventions (Wolf & Katzir-Cohen, 2001), features and research on fluency practices (Kuhn & Stahl, 2003), and the findings on fluency interventions for children with learning disabilities (Chard et al., 2002). In their review of the history of fluency interventions and their components, Wolf and Katzir-Cohen described a theory-based, multi-component fluency intervention based on information processing models (LaBerge & Samuels, 1974; Perfetti, 1985) that predict that fast acting subskills enable students to allocate sufficient attention to higher level text comprehension. Wolf and Katzir-Cohen described more recent research that captures both the developmental nature of fluency (Kame'enui et al., 2001) and multiple processing systems (phonological, orthographic, and morphological) that contribute to text-level reading fluency. This review highlighted several important limitations. First, most interventions were relatively short—between 1 and 15 days in length. More recent research has underscored the difficulty of remediating students with poor fluency (i.e., Torgesen et al., 2001) and the need for intensive intervention. Second, most of the studies in this review did not include a control group. Third, comprehension was assessed inconsistently. And fourth, studies did not examine lexical-level rate

change that may be most directly influenced by repeated reading (Faulkner & Levy, 1999; Torgesen et al., 2001).

Kuhn and Stahl (2003) identified 15 studies of repeated reading that included a control group. They found that repeated reading intervention was more effective than the control condition in six studies and in one study only when familiar passages were used. Considering findings of effectiveness based on individual study comparisons (adding weight to studies with multiple comparisons), they found that repeated reading interventions were significantly more effective than control conditions in 8 comparisons and not more effective in 21 comparisons. Differences in types of control groups used in these studies (no treatment or nonrepeated reading control) made it difficult to draw firm conclusions across these studies. Kuhn and Stahl found some advantage for reading more difficult text and that comprehension gains were difficult to detect using standardized comprehension measures (rather than cloze tasks).

Finally, Chard et al. (2002) reviewed 24 studies of fluency interventions provided for elementary students with learning disabilities. They found that repeated reading with a model was most effective, particularly for students with low fluency. A teacher or adult model was more helpful than a tape or computer model. Fluency growth was associated with comprehension growth in many of the studies. Although findings did not suggest an optimal number of rereadings, the authors concluded that effective components of fluency intervention for students with learning disabilities include rereading difficult text with adult feedback and corrections. The study design we describe here addresses limitations in research designs found in these earlier reviews of fluency interventions, including lack of a control group, low intensity of treatment, and lack of standardized word reading efficiency and comprehension measures.

### Intervention Research on Supplemental Instruction

Supplemental reading interventions play an important role in many children's reading instruction. They may be provided by teachers or by paraeducators, and in individual or small-group, pull-out sessions. A small number of these interventions, particularly early phonological awareness and phonics-based programs, have been evaluated in rigorous research designs (*Road to the Code*: Blachman, Ball, Black, & Tangel, 1994; Blachman, Tangel, Ball, Black, & McGraw, 1999; *Ladders to Literacy*: Fuchs et al., 2001, 2002; *Peer Assisted Learning Strategies*: Fuchs et al., 2001, 2002; *Spell Read P.A.T.*: Rashotte, MacPhee, & Torgesen, 2001). There is limited research on supplemental instruction using programs that focus on fluency skills (*Read Naturally*: Hasbrouck, Ihnot, & Rogers, 1999; *Great Leaps*: Mercer, Campbell, Miller, Mercer, & Lane, 2000). Because the fluency intervention in the present study was used to supplement classroom instruction and was implemented by paraeducator tutors, we consider features associated with effective supplemental tutoring interventions. Juel (1996) summarized reading activities significantly associated with literacy growth in tutoring programs, including direct letter-sound instruction and the introduction of high-frequency and pattern words. Wasik's (1998b) review of 17 studies of volunteer tutoring in reading skills identified four features common to programs: a designated coordinator with a background in reading instruction; structured tutoring sessions that included reading new material,

reading familiar books, and focusing on word analysis and alphabets; writing composition; and tutor training. Wasik (1998a) and others (Jenkins & Jenkins, 1987; Reisner, Petry, & Armitage, 1990; Venezky & Jain, 1996) also recommended that tutoring be coordinated with classroom instruction, although well-designed studies on this issue are lacking. The fluency intervention we describe includes many features identified in effective tutoring programs: a structured format, a focus on alphabets and high-frequency words, tutor training, and tutor scaffolding and modeling.

Research on paraeducator-supplemented instruction provides another source of information on effective tutoring. It includes studies of kindergarten and first-grade literacy interventions implemented by instructional assistants (Blachman et al., 1994; Gunn, Biglan, Smolkowski, & Ary, 2000; Gunn, Smolkowski, Biglan, & Black, 2002; Gunn, Smolkowski, Biglan, Black, & Blair, 2005; Simmons, Kame'enui, Stoolmiller, Coyne, & Harn, 2003; Torgesen, Wagner, Rashotte, et al., 1999; Vadasy, Jenkins, & Pool, 2000; Vadasy, Sanders, & Abbott, in press; Vadasy, Sanders, Jenkins, & Peyton, 2002; Vadasy, Sanders, & Peyton, 2006). Critical features of effective paraeducator-implemented instruction include training and research-based standard treatment protocols that paraeducators can learn to use with fidelity.

### Research Questions

This study was designed to assess effects of a repeated reading intervention, *Quick Reads* (Hiebert, 2003), with incidental word-level scaffolding instruction on student gains as compared to regular classroom reading instruction. Research questions were the following:

1. What are the direct effects of this intervention, provided by paraeducators to pairs of second- and third-grade students with low to average passage-reading fluency (PRF), on students' word reading, fluency, and comprehension gains?
2. What are the unique effects of this intervention after accounting for classroom oral text reading (OTR) time, pretest rapid automatized naming (RAN), and pretest word reading accuracy? Are treatment effects moderated by these variables?

We expected the greatest reading fluency gains to occur for students with stronger initial word reading accuracy, as well as for students who received more classroom oral reading practice (relative to their peers). Additional oral reading practice might boost fluency development; although as Berninger et al. (2001) suggested, subtypes of students with poor fluency may require differential treatments to address specific problems in lexical retrieval and coordination of language processes. We were unable to identify subtypes of fluency deficits in this study, and we assumed that classroom oral reading practice opportunities would generally benefit fluency outcomes. We therefore collected information on text reading opportunities provided during classroom reading instruction for both treatment and control students, hypothesizing that these activities might benefit both groups.

For descriptive purposes, we also recorded classroom instructional time allocated to word identification and comprehension

skills, as well as organizational features of classroom reading instruction, such as grouping and use of time (Cameron, Connor, & Morrison, 2005). Findings from recent studies using classroom observational systems (Connor, Morrison, & Katch, 2004; Connor, Morrison, & Petrella, 2004; Foorman, Francis, Fletcher, Schatschneider, & Mehta, 1998; Taylor, Pearson, Peterson, & Rodriguez, 2005) have suggested that reading instruction varies along several dimensions across classrooms, including grouping strategies, time spent on salient instructional activities, and the interaction of classroom instruction and student skill levels. As Smith and Siegel (2006) noted, attention to routine practice conditions may inform how to best scale up effective reading interventions. In this study paraeducators rather than researchers were used to implement instruction, and a high fidelity of implementation was sought.

### Method

#### Participants

*Student referral and screening.* In the fall of the academic year, second- and third-grade teachers from 13 urban, public elementary schools were asked to refer students who (a) had never been retained, (b) had low rates of reading fluency or comprehension, and (c) would benefit from a fluency intervention (i.e., students with adequate word reading skills to benefit from fluency instruction). Once active parent consents were obtained, referred students were screened for eligibility using two grade-level passages from the Oral Reading Fluency subtest of the Dynamic Indicators of Basic Early Literacy Skills (Good & Kaminski, 2002). Students whose performance was in the 10th to 60th percentile range (approximately averaging 34th percentile) for their grade level on the mean of the two passages were considered eligible for participation (60th percentile was approximated by solving for the respective fluency rate value corresponding to  $Z = 0.25$ ; Hasbrouck & Tindal, 2006). This performance range was specifically 11 to 62 words correct per minute (wcpm) for second graders and 21 to 82 wcpm for third graders. Teachers referred students with a wide range of fluency for study participation. It should be noted that by Grades 2 to 3, reading rate becomes an important reading target in schools. As a result, many students had low rates of reading fluency and below-grade-level decoding skills.

*Group assignment.* Group assignment was a two-stage process. First, eligible students were randomly assigned to dyads (pairs of students) within grade and school using a random number generator. Although it would have been preferable to randomly assign students to dyads within classrooms in order to minimize extreme mismatches between students within a dyad, there were too few eligible students within classrooms to make this practical. Nevertheless, there were sufficient numbers of eligible students for random assignment of dyads within grades (within schools). For schools with uneven numbers of students within grades, we used random selection to identify singletons that were subsequently excluded from participation. Dyads were then randomly assigned to one of two conditions: treatment (supplemental fluency tutoring instruction) or control (no tutoring; classroom instruction only).

*Attrition.* After group assignment, the sample comprised 96 students (48 dyads) in the treatment condition and 92 students (46

dyads) in the control condition. By the end of the study, 14 treatment and 12 control students were lost to attrition (14%). To ensure an operational definition of treatment as well as an unbiased attrition pattern across treatment and control groups, we removed any dyad member from study participation if the corresponding member moved from the school. (Although control pairs did not necessarily receive reading instruction together, we assumed that control pairs shared common reading curricula due to the within-grade, within-school pairings.) The sample used for analyses thus comprised 82 treatment students (41 dyads) and 80 control students (40 dyads). As reported in Table 1, there were no significant differences between groups on grade or status variable frequencies (all  $ps > .05$ ).

**Tutors.** A total of 22 tutors were recruited from their school communities. Tutors' educational levels, general tutoring experience, and experience working with second and third graders varied. All but one had already been working at the school as either an instructional assistant or tutor. Prior to the study, tutors had a range of 0 to 11 years of reading tutoring experience ( $M = 3.6$  years,  $SD = 3.43$ ), and all tutors had at least a high school diploma (15 had bachelor's degrees, 5 with teaching certificates). The average educational attainment of tutors in this study matched the paraeducator competency requirements under the No Child Left Behind Act of 2001. Most tutors (91%) were female, and six (27%) were of minority heritage.

### Intervention

Treatment students received supplemental tutoring in dyads for 30 min per day, 4 days per week, for 15 weeks (November to March) using the *Quick Reads* (Hiebert, 2003) fluency program. Students assigned to the control group received regular classroom instruction, whereas treatment students received tutoring in their respective pairs. Classroom teachers reported that most treatment students ( $n = 58$ , or 70%) missed some portion of classroom reading instruction. For 15 students (18%), the *Quick Reads* intervention served as added reading instruction time: These students typically missed the nonreading activities and instruction such as chess club, computer lab, math, physical education, science, and

social studies. Teachers of 9 students did not report the instruction missed during tutoring.

The *Quick Reads* program includes short, nonfiction passages written for grade levels 1 to 6. Each grade level includes nine topics based on national and state curriculum standards for science and social science. Five passages are written to develop knowledge about each topic. For example, for Level B (second grade), science topics include "Water and Us," "Weather," and "Rocks." Level B social studies topics include "Maps," "Money," and "Jobs Around Us." An important feature of the *Quick Reads* program is its attention to text features to build fluency and comprehension. The number of unique or different words is minimized, and 98% of words used in the texts are high-frequency words or words that reflect grade-level phonics and syllable patterns. Repeated word exposures are designed to build sight word learning. Rare words and singletons are minimized, as students are unlikely to acquire these words as sight words from single exposures and are unlikely to practice them in classroom texts. These text characteristics are hypothesized to develop underlying lexical accuracy and automaticity skills often overlooked in traditional repeated reading remedial interventions.

*Quick Reads* is designed for classroom or small-group use, either in regular reading instruction or as a supplemental intervention. The number of passages students cover daily and the length of the intervention depend on how it is used. If a teacher follows the recommended classroom instructional routine, students use *Quick Reads* for 15 min a day for one semester, or 18 weeks. Each passage is read three times:

1. First read. The teacher activates background knowledge about the topic and asks students to find two words that are challenging. Students read the passage aloud or silently and then write notes or phrases of key ideas.
2. Second read. The teacher reads aloud with the students, setting a model for fluent reading, all reading aloud at the target rate of 1 min. The teacher asks students to "tell the one thing the author wants you to remember."
3. Third read. The teacher instructs students to read as much of the passage as they can read in 1 min. The students then read silently for 1 min, and when the time is up each student records the number of words read. The teacher and student review two comprehension questions together.

The teacher's manual from the *Quick Reads* program outlines placement procedures for students with passage-reading performance of (a) at least 90% accuracy and at least a rate of 50 words per minute (wpm), (b) less than 90% accuracy or a rate of less than 50 wpm, and (c) less than 90% accuracy and a rate of less than 50 wpm. For students in the last category, the manual suggests a modified instructional routine that might include instruction in word reading skills. The manual also suggests teaching options to develop vocabulary, word identification, and comprehension skills. For example, activities are suggested for teaching vocabulary or identifying the main idea of the passage.

**Tutoring sessions.** Rather than expect tutors to choose an appropriate activity to add to the repeated reading steps, we created

Table 1  
Student Characteristics

Characteristic	Treatment		Control		$\chi^2(1, N = 162)$
	N	%	N	%	
Grade 2	58	70.7	52	65.0	0.61
Male	47	57.3	51	63.8	0.70
Minority	56	68.3	57	71.3	0.17
Asian	16	19.5	10	12.5	
Black	22	26.8	23	28.8	
Hispanic	15	18.3	22	27.5

English-language learner	19	23.2	18	22.5	0.01
Special education	13	15.9	15	18.8	0.24
Title 1	63	76.8	58	72.5	0.40

Note. Treatment group ( $N = 82$ ), control group ( $N = 80$ ). Chi-square tests of independence were used to compare categorical frequencies between groups. All  $ps > .05$ .

an instructional package similar to what is suggested in the *Quick Reads* manual. The teacher manual is written for classroom or small-group instruction and assumes that the teacher chooses the enrichment activities, coordinated with student need and other reading instruction. We added brief word-level instruction to meet the needs of the many students with low word reading skills who were referred for study participation, and we allowed tutors up to 5 min per session for this instruction as needed. (We also measured the amount of phonics/word study instruction provided in the classroom to understand better how the intervention coordinated with classroom instruction for low decoders in particular.) All instruction for this intervention was scripted, as described here, to ensure instructional consistency. Each tutoring session had six steps, as follows:

1. Letter/sound practice. Previous experience with an earlier cohort of *Quick Reads* students (Vadasy & Sanders, in press) led us to expect that second- and third-grade students with poor fluency would benefit from brief instruction and review in the alphabetic principle, particularly two-letter spelling patterns, as well as supportive correction strategies for their word miscues. Although this extension activity is not specifically suggested in the teacher's manual, we believed it would strengthen the program for the less skilled students in this study, and it was brief enough not to weaken the recommended intensity of the *Quick Reads* instruction (recommended for 12- to 15-min sessions to cover one passage). We therefore designed and scripted an extension activity for this *Quick Reads* field test that allowed tutors to review letter sounds if needed and provide scaffolded assistance in decoding difficult words. For up to 5 min of each session, tutors used a set of letter sound cards to review and practice accurate and automatic letter-sound correspondences, including vowel teams and consonant blends. Tutors were instructed to provide this practice only for letters and sounds that were problematic for students. If the student could not yet identify the sounds, the tutor directed the student to point to the letters on the cards and say the letter name, picture cue, and letter sound. For letters the student could not automatically match with a sound, the tutor pointed to the letters and asked the student to say the sounds. Time for review was allotted to each student as needed.

Tutors were also trained to provide scaffolding for word reading attempts with graduated levels of assistance to encourage students to apply their alphabetic and decoding skills. Corrective and supportive strategies the tutors used included (a) referring to the letter sound card to retrieve a letter sound, (b) encouraging the student to stretch out the sounds and then say the word fast, (c) assisting the student in segmenting a multisyllable word and then putting the parts together, and (d) telling the student an irregular nondecodable word and having the student reread the word.

2. First passage reading. Tutors introduced the main idea for the first passage, and students skimmed the passage to find difficult words to practice before passage reading. Students then took turns reading and following along with their finger.

3. Second and third passage reading. Both the tutor and students read the passage aloud together twice, with the tutor modeling smooth, accurate, and fluent reading.

4. Fourth passage reading. Each student completed a 1-min timed reading for which the tutor recorded the students' reading rates and accuracies.

5. Comprehension. Tutors and students discussed two comprehension questions.

6. Reading of new passage/rereading of previous passage(s). As time permitted, students reread the previous passage or began a new passage (following the first five steps outlined previously). Students completed Steps 1 through 5 for at least two passages per session.

*Quick Reads placement and coverage.* *Quick Reads* passages are organized by grade level (A = first grade, through F = sixth grade). Each *Quick Reads* level has three books, and each book contains six content areas with five passages per content area, for a total of 90 passages per level. We placed dyads into levels based upon the grade level for which their average pretest reading fluency most closely matched 50th percentile (Hasbrouck & Tindal, 2006). Our sample, after attrition, included 29 dyads placed into Level B and 12 dyads placed into Level C. One dyad originally placed in Level B was moved back to Level A, but all other dyads moved forward to Levels C or D after completing the previous level.

For each student's session, tutors recorded attendance, including the *Quick Reads* passage(s) covered and the fluency rate and accuracy for each timed reading. Treatment students completed an average of 95 passages ( $SD = 18.2$ ), attended an average of 50 tutoring sessions ( $SD = 5.8$ ) or 25 hr of intervention, and averaged 1.9 passages read per session ( $SD = 0.23$ ; range = 1.5–2.9). To determine the difficulty level of the passages students read, we computed the accuracy rate across all attended sessions on *Quick Reads* levels. On average, students read at 95% accuracy within Level A and at 97% accuracy within Levels B, C, and D. These estimates suggest that the students read relatively difficult text at an instructional level for which students needed assistance. More difficult repeated reading materials may be associated with greater fluency improvements (Kuhn & Stahl, 2003).

*Tutor training.* Tutors participated in one initial 4-hr training session by project staff. Training included an overview of reading fluency development and the repeated reading method. Research staff then modeled the use of *Quick Reads* materials and demonstrated procedures for adding instruction/scaffolding in decoding. The tutors practiced the protocols during training and received immediate feedback. Following this training, coaches visited tutors biweekly to provide follow-up training and modeling and to collect data on protocol fidelity.

*Tutor coaching.* Throughout the 15-week intervention, research staff supported and conducted observations of the tutors. Researcher coaches were assigned to specific tutors and conducted a minimum of six observations on each tutor (at least two observations per dyad). Coaches met monthly to discuss tutoring implementation progress.

*Tutor observations.* To monitor treatment implementation fidelity, we collected data via observation forms on (a) tutor adherence to scripted *Quick Reads* protocols, (b) tutor instructional behaviors, and (c) student progress in terms of the amount of time spent actively engaged in reading passages. Tutors' fidelity to protocols was measured using a 5-point rating scale of 1 (*never*) to 5 (*always*) for each intervention step previously described. Tutor instructional behaviors were measured using the same 5-point scale for six criteria that included "maximizes time on instruction," "quick pace/smooth transitions/minimal pauses," "uses appropriate specific praise," "materials are organized," "maintains accurate

attendance records,” and “provides appropriate error correction/scaffolding.” Student progress was measured by recording the amount of time (in seconds) students were orally reading text. Prior to onsite tutor observations, we established interobserver reliability among the five researcher-observers using five videotaped *Quick Reads* sessions. Each observer viewed and rated each taped session using the observation criteria. From these ratings, interobserver reliabilities were computed. Internal consistency for the five raters was .88 for tutoring protocol fidelity and .90 for tutor instructional behaviors. Reliability for text reading time ranged from .88 to 1.00 and averaged .95 (all  $ps < .05$ ). Across 170 observations (approximately 8 per tutor and 4 per dyad), adherence to protocols averaged 4.76 ( $SD = 0.20$ ) and tutor instructional behaviors averaged 4.76 ( $SD = 0.18$ ). Each student (within their dyad) spent an estimated average of 10.4 min per session ( $SD = 3.16$ ) actively engaged in oral reading.

### Student Assessments

Students were individually assessed by trained testers unaware of group assignment on RAN and four reading subskills that were hypothesized to be differentially affected by intervention: word reading accuracy, word reading efficiency, fluency, and comprehension. Except for two submeasures of fluency, norm-referenced standard scores were used for analyses. In the measure descriptions that follow, published reliabilities are provided, as well as reliabilities for our sample (internal consistencies are Cronbach's alpha).

1. RAN was measured at pretest only using the Letter Naming subtest of the Rapid Automatized Naming/Rapid Alternating Stimulus tests (Wolf & Denckla, 2005). For this subtest, students were presented with a card that had five randomly sorted letters (*a, d, o, p, s*) repeated 10 times each and were asked to say the names of the letters as quickly as they could. The raw score was the total number of seconds the student used to name all of the letters. Test-retest reliability reported in the test manual is .87 for elementary grades. We also measured students on the Number Naming subtest to obtain concurrent validity: The correlation between Letter Naming and Number Naming (in number of seconds) was .79.

2. Word reading accuracy was measured using the Word Identification subtest from the norm-referenced, standardized Woodcock Reading Mastery Test—Revised/Normative Update, Form H (Woodcock, 1987/1998). Students were required to read increasingly difficult words, and testing was discontinued after six consecutive incorrect responses. Split-half reliability reported in the test manual averages .99 for Grades 1 to 3. Internal consistencies for our sample were .94 at pretest and .92 at posttest.

3. Word reading efficiency was measured using the Sight Word subtest from the norm-referenced, standardized Test of Word Reading Efficiency, Form B (Torgesen, Wagner, & Rashotte, 1999). The Sight Word subtest required students to read as many words as possible in 45 s from a list of increasingly difficult words. Test-retest reliability reported in the test manual for 6- to 9-year-olds is .96. For our sample, internal consistencies were .94 at pretest and .95 at posttest.

4. Fluency was the primary skill targeted in the intervention and was assessed two ways: in a raw-score framework as PRF and in a norm-referenced framework as fluency rate. Although a norm-

referenced measure of fluency can provide a generalizable measurement of students' fluency rate, we considered PRF—in terms of wcpm performance—to be a meaningful indicator of students' responsiveness to intervention. Thus, we measured students' PRF using two passages drawn from the Dynamic Indicators of Basic Early Literacy Skills: one grade-level passage used at each test interval (uniform passage; for second graders, this was “If I Had a Robot,” and for third graders, this was “My Friend”) and one grade-level alternate passage at each test interval. Alternate passages for second graders included “Roller Coaster” and “Drift Bottle”; for third graders, alternate passages included “Fieldtrip” and “Parents.” For each passage, students read aloud while the tester recorded errors, and testing was discontinued after 1 min. Words omitted, words substituted, and hesitations of more than 3 s were scored as errors. For our sample, the correlations between the uniform second- and third-grade passages were .88 and .91 at pretest and posttest, respectively, and the correlations between the uniform and alternate passages were .84 and .86 for pretest and posttest, respectively. Across passages, internal consistencies (using words as items) ranged from .96 to .98.

We assessed PRF using both uniform (PRF-U) and alternate (PRF-A) passages to minimize measurement error from potential passage nonequivalence effects (by using a uniform passage) and potential passage memory effects (by using alternate passages). Although the use of a uniform passage introduces potential memory effects (i.e., the student may remember words in a passage read on a previous occasion and thereby be able to read the text faster; or the student may remember the story structure, which may prime faster text reading) and low generalizability (i.e., the uniform passage has a specific vocabulary and story structure that differ from other passages), any memory effects occurring for treatment students have an equal chance of occurring for control students. Whereas estimates of true gains across all students on the uniform passage would likely be inflated, estimates of treatment effects on gains using the uniform passage should be free of nonequivalence effects. Consistent with our reasoning, Jenkins, Zumeta, and Dupree (2005) found that use of uniform passage measurements (compared to alternate passages) measured fluency gains more reliably; however, memory effects were detected for the uniform passage at the 5-week retest.

Our second, norm-referenced, assessment framework for measuring fluency included the Rate subtest from the Gray Oral Reading Tests—4 Form B (GORT; Wiederholt & Bryant, 2001). For this subtest, students read passages aloud, beginning at their grade level. Performance on the grade-level passage determined whether students subsequently read a lower or higher level passage, and testing was discontinued when a basal and ceiling were established. The amount of time it took students to read each passage converted to a raw score, ranging from 0 to 5 for each passage read. To be consistent with our other norm-referenced measures, we transformed the GORT standard score distribution with a mean of 10 and standard deviation of 3 to have a mean of 100 and standard deviation of 15. Cronbach's alpha reported in the test manual is .92 for 7- to 8-year-olds. Sample internal consistencies were .84 at pretest and .91 at posttest.

5. Comprehension was assessed at pretest and posttest with the GORT Comprehension subtest. Students read passages aloud, beginning at their grade level, and were asked comprehension questions for each passage. Performance on the grade-level passage

determined subsequent passage reading, and testing was discontinued when a basal and ceiling were established. Standard scores were transformed to have  $M = 100$  and  $SD = 15$ . Alternate form reliability reported in the test manual is .96 for 7- to 8-year-olds. Sample internal consistencies were .83 at pretest and .89 at post-test.

### *Classroom Literacy Instruction Observations*

We hypothesized that a specific dimension of classroom literacy instruction would interact with group assignment: time spent on OTR. For example, teachers who spend more time on OTR may bolster control students' fluency skills in the same manner as that expected for treatment students. We therefore endeavored to quantify the classroom literacy instruction for all students in the intervention study. Fifty-two classroom teachers (or reading/resource room teachers, as some students received regular reading instruction with these teachers) were asked for permission to allow us to observe their midyear reading instruction on two separate occasions (approximately 1 month apart, in one of three combinations: December/January, January/February, or February/March). Six (12%) declined to participate.

**Observation tool.** We used an adapted version of the *Instructional Content Emphasis—Revised* (ICE-R; Edmonds & Briggs, 2003) for measuring classroom literacy instruction. The standard ICE-R includes the following four dimensions: main instructional category, grouping arrangement, instructional subcategory, and materials used. We simplified the measure because establishing interobserver reliability across all dimensions would have been enormously challenging. We therefore collected data on the first two dimensions only: main instructional category and grouping arrangement.

The main instructional category measures instructional time spent on 10 mutually exclusive literacy activities: concepts of print, phonological awareness, alphabetic knowledge, word study/phonics, spelling, oral language development, fluency building, text reading, comprehension, and writing/language arts. After reviewing sample classroom reading instruction videotapes, we identified the need for four additional mutually exclusive instructional activity codes: behavior management, evaluative feedback, transition time, and other types of nonliteracy instruction (i.e., math instruction). Activities coded as behavior management included the teacher reminding students of behavior consequences, reinforcing good behavior, and talking to students who were inattentive or off task. Activities coded as evaluative feedback included explaining procedures for an instructional task and providing error correction feedback. Activities coded as transition time included students putting materials away, cleaning up, waiting, and lining up.

In addition to these 14 activities, we purposefully added a code to measure instructional time spent on OTR. Although OTR overlaps with the activities described previously (in particular, fluency building and text reading), we wished to capture time specifically afforded to OTR opportunities similar to those in *Quick Reads* instruction (in contrast to fluency building, which includes repeated word reading; and text reading, which includes silent reading practice).

The grouping arrangement dimension, which overlapped with the main instructional category activities, measured the amount of

time the teacher grouped students for instruction in whole class, small-group, pair, independent, and individualized arrangements. During each of these instructional formats, students' overall level of engagement was rated using a 3-point rating scale (1 = *low*, 2 = *moderate*, and 3 = *high engagement*).

**Recording process.** Observations were conducted for the entire duration of teachers' literacy blocks. Observers began timing at the beginning of the observation. When instruction began, observers coded the teacher's first instructional activity, and thereafter recorded each clock time (running forward from zero) associated with instructional change, along with the appropriate instructional codes. Time entries and codes were entered into a database, and the time spent on each code was computed automatically for each teacher for each observation occasion.

**Observers and reliability.** Three certificated teachers who were tutor observers also served as classroom instruction observers. Each observer studied the ICE-R manual and coding instructions and participated in several training sessions to review the measure. Observers were trained by Patricia F. Vadasy, and, to establish reliability (prior to onsite observations), observers used the ICE-R to code one 60-min videotape of language arts instruction for a first-grade classroom at one of the schools participating in the study (first grade was used because we did not wish to bias potential observations of second- and third-grade classroom teachers). To calculate reliability, we sectioned total videotape time (60 min) into 10-min intervals (the first 10 min, the second 10 min, etc.) and treated each interval as one observation. For each observer, time spent on each activity per observation was computed. Interobserver correlations were .70 or higher, and Cronbach's alpha ranged from .79 to .99.

**Observation results.** Although we had planned to conduct three observations of each classroom's literacy block, coordinating teachers' schedules with those of our small group of observers proved extraordinarily difficult. Our compromise was to conduct two observations per teacher. For each teacher, the length of time spent on each activity was averaged across the two observations. Table 2 provides a summary of teachers' average midyear time spent on each activity from the first dimension (main instructional category). Literacy blocks ranged from 32 to 132 min and averaged 76.6 min ( $SD = 21.03$ ). On average, teachers spent the majority of their time on comprehension (27% of the average amount of time), text reading, and transitioning students from one activity to another. As was expected of second- and third-grade reading instruction, teachers spent the least amount of time on concepts of print, phonological awareness, and alphabetic knowledge (i.e., less than 30 s). Eighty-five percent of average OTR time (11.9 min) overlapped with average text reading time; in other words, 66% of general text reading time was OTR. The remaining 15% of average OTR time overlapped with word study (3%), fluency building (3%), comprehension (4%), writing (3%), and evaluative feedback (3%). Teachers primarily grouped students for whole-class ( $M = 29.8$  min,  $SD = 19.35$ ) or small-group ( $M = 18.1$  min,  $SD = 18.05$ ) instruction. Teachers were also observed implementing paired (4.2 min, 5%), independent (7.6 min, 10%), and individualized (9.6 min, 13%) instructional grouping. Finally, students were observed as having high engagement 68% of the time (51.9 min) and moderate engagement 15% of the time on average. Low engagement was rare at 4% of the time.

Table 2  
Classroom Literacy Instruction Observations: Characteristics for Primary Dimension Subtypes

Name	Description	M	SD	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
1. Concepts of print	Print directionality, book parts, text features	0.3	0.86	—														
2. Phonological awareness	Rhyming, syllable or phoneme blending, segmenting, isolating	0.2	0.89	-.03	—													
3. Alphabets	Letter identification and recognition	0.2	1.27	-.05	-.04	—												
4. Word study	Phonics, letter identification and recognition, decoding, sight words	6.3	7.58	-.21	-.05	-.15	—											
5. Spelling	Oral or written spelling, practice with patterns	0.9	1.87	<b>.60</b>	-.10	-.06	-.14	—										
6. Oral language	Teacher and students discuss words, books, songs, topics	1.6	2.39	.26	-.02	.17	.04	.04	—									
7. Fluency building	Students read aloud to build speed; accuracy; prosody for letters or sounds, words, text	0.8	1.73	.08	-.08	.08	.23	-.03	-.06	—								
8. Text reading	Students read orally or silently with class, small groups, individually	17.9	10.06	<b>-.31</b>	-.17	.01	.22	-.09	-.17	.19	—							
9. Comprehension	Vocabulary, prior knowledge, monitoring understanding, strategy instruction	21.0	12.64	.05	-.21	.06	-.16	.12	-.09	-.01	.13	—						
10. Writing	Composition, independent or group, mechanics, handwriting	5.0	7.18	.11	-.06	.03	.05	-.04	.09	-.01	-.26	<b>-.41</b>	—					
11. Behavior	Noninstructional time to manage behavior	1.3	2.61	-.10	-.09	.05	.02	-.11	-.07	-.08	.16	-.16	-.02	—				
12. Error correction	Teacher feedback on student errors, miscues	8.7	6.58	-.03	.12	.03	-.08	-.10	-.12	.09	-.22	<b>-.32</b>	<b>.38</b>	.01	—			
13. Other	Nonreading instruction (e.g., math concepts)	0.9	2.17	.08	-.09	-.07	-.17	.02	-.07	-.19	-.06	.05	.00	-.15	-.15	—		
14. Transitioning	Time to gain students' attention on tasks, to reorganize, or to move groups	11.5	5.06	-.03	.02	.03	.27	.17	-.17	.14	<b>.43</b>	.01	-.08	.28	-.03	-.24	—	
15. Oral text reading	Students working with teacher are reading aloud	14.0	8.79	-.22	-.21	.26	.20	-.10	-.17	<b>.33</b>	<b>.47</b>	-.08	-.18	.03	<b>.30</b>	—	-.22	.23

Note. *N* = 46 teachers; 6 teachers missing data. All categories are nonoverlapping, except oral text reading; number of minutes of literacy block reported, calculated as the average from two separate midyear observations (1 month apart). Pearson's *r* is reported; statistically significant correlations at the .05 level are in bold.

Results

Data Analysis Strategy

Due to nesting structures present in our research design, a multilevel (hierarchical) modeling approach was adopted for analyzing group differences on pretests and gains. Specifically, we tested group differences on pretests using two-level models (students within classrooms) with group dummy coded (1 = treatment and 0 = control). Two-level models were also used to analyze pretest–posttest gains; for these analyses, group was effect coded (1 = treatment and –1 = control) in order to test treatment interactions. Pretest–posttest gains were analyzed two ways: The first set of analyses tested the direct effects of the treatment on outcomes, and the second set tested the unique effects of the treatment in the presence of classroom OTR time and pretest RAN and word reading accuracy, which effectively excluded 13 students whose teachers declined observation. For the second set of models, OTR and pretest scores were grand-mean centered for ease of interpretation. In both sets of models, we ignored dyad membership because (a) assignment to dyads was cross-classroom; (b) we reasoned that dyad membership would have less impact on gains than classroom reading instruction (particularly for controls); (c) we wished to test cross-level classroom OTR effects on outcomes; and (d) although a cross-classified multilevel model can account for dyad and classroom nesting structures, cross-classified models are far more complex than hierarchical models. For all hierarchical analyses, HLM was used (Raudenbush & Bryk, 2002; Raudenbush, Bryk, Cheong, & Congdon, 2004; Rodenbush, Bryk, & Congdon, 2004); all other analyses were conducted in SPSS (1989–2004).

Pretests

Observed group means and standard deviations are reported in Table 3. According to Hasbrouck and Tindal (2006) norms, students ranged from the 10th to the 60th percentiles and averaged the 34th percentile on pretest PRF performance. According to stu-

dents’ fluency rate scores from the GORT (Wiederholt & Bryant, 2001), however, the sample averaged in the lower 10th percentile. Pretests also showed that the sample averaged in the lower 25th percentile in RAN, lower 40th percentile in word reading accuracy, lower 25th percentile in word reading efficiency, and lower 20th percentile in comprehension.

Results from our hierarchical pretest models revealed one significant difference between groups at study onset: The control group was 2.2 points higher than the treatment group on pretest word reading accuracy,  $t(160) = -2.262, p < .05$ . As expected, model results also showed significant variation between classrooms on both PRF measures and the norm-referenced fluency rate (chi-square test  $p$  values  $< .001$ ); nevertheless, no reliable between-classroom variance was detected for pretest word reading accuracy, word reading efficiency, or comprehension.

Treatment-Related Relationships

We explored the relationships between treatment students’ pretest–posttest gains and treatment-related variables, including *Quick Reads* passages read, rates of passages read per session, and whether students missed classroom reading instruction during tutoring (the majority of students were pulled out for 30 min of the typical 90-min literacy block). As shown in Appendix A, none of these variables were significantly related to student outcomes. (Although not shown in Appendix A, neither total hours of instruction nor tutor fidelity ratings were correlated with gains.) OTR, in contrast, positively affected gains on all measures except comprehension, regardless of group (see Appendix B).

Direct Treatment Effects on Pre–Post Gains

Results from our hierarchical linear models for pretest–posttest gains revealed that students’ average conditional gains were significantly greater than 0 across all measures (all  $t$ -test  $p$  values  $< .05$ ; see Table 3 for observed mean gains). Direct treatment effects were detected for gains on word reading accuracy and all three

Table 3  
Observed Pretests, Posttests, and Pretest-Posttest Gains

Measure	Treatment						Control					
	Pretest		Posttest		Gain		Pretest		Posttest		Gain	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
RAN	87.7	10.12					90.5	9.99				
WR accuracy	94.3	7.63	97.8	7.04	3.5	5.66	96.5	6.09	98.3	6.25	1.8	5.29
WR efficiency	87.9	9.19	94.7	10.12	6.8	7.72	89.2	8.50	94.6	10.49	5.5	8.09
PRF-U	40.0	18.35	83.1	22.27	43.2	16.53	42.3	19.91	79.0	23.76	36.7	19.56
PRF-A	37.5	16.84	68.3	26.38	30.8	18.50	39.6	17.13	62.5	26.63	22.9	18.36
Fluency rate	77.0	8.23	88.6	13.13	11.6	9.62	78.6	8.07	86.8	12.10	8.2	9.25
Comprehension	84.8	13.09	92.8	15.72	8.0	13.74	87.6	13.71	92.9	16.22	5.4	16.12

*Note.* Treatment group  $N = 82$ , control group  $N = 80$ . Norm-referenced standard scores (raw scores adjusted for age) were used for all measures except PRF-U and PRF-A; for these two measures, words correct per minute were used. The control group performed significantly higher on the WR accuracy pretest. RAN = Letter Naming subtest from the Rapid Automatized Naming/Rapid Alternating Stimulus tests; WR accuracy = Word Identification subtest from the Woodcock Reading Mastery Test—Revised/Normative Update; WR efficiency = Sight Word subtest from the Test of Word Reading Efficiency; PRF-U and PRF-A = words-correct-per-minute performance on uniform and alternate passages, respectively, from the Oral Reading Fluency subtest from the Dynamic Indicators of Basic Early Literacy Skills; Fluency rate = Rate subtest from the Gray Oral Reading Tests-4 (GORT); Comprehension = GORT Comprehension subtest.

fluency measures but not for word reading efficiency or comprehension: On average, students in the treatment group gained 1.6 more standard score points than controls on word reading accuracy,  $t(160) = 2.206, p < .05$ ; and 2.6 more points on fluency rate,  $t(160) = 2.537, p < .05$ . On PRF-U, treatment students had an estimated 5.8-wcpm advantage over controls,  $t(160) = 2.276, p < .05$ ; and a 7.9-wcpm advantage on PRF-A,  $t(160) = 3.008, p < .01$ . Model results also revealed significant between-classroom variation on gains for all measures except comprehension (chi-square test  $p$  values  $< .05$ ). Taking the square root of the total estimated variance (between-classroom + residual variance) as a pooled standard deviation, we calculated approximate treatment effect sizes (Cohen's  $d$ ) and found  $d = .29, .31, .32$ , and  $.43$ , for gains in word reading accuracy, fluency rate, PRF-U, and PRF-A, respectively.

### *Conditional Treatment Effects on Pre-Post Gains*

Our second, more complex set of hierarchical models tested the unique effect of treatment on student gains in the presence of classroom OTR time, pretest RAN, pretest word reading accuracy (WR), and corresponding interactions. As a reminder, these analyses excluded 13 cases due to the six teachers who declined to participate in classroom observations. As a check on the potential bias introduced into our models due to excluding these cases, we compared students who were excluded with those who were included and found no differences between groups on any variable included in our models: All  $t$ -test  $p$  values  $> .05$  for RAN, WR, and all gains. As shown in Table 4, results from these models revealed significant unique treatment effects on word reading efficiency (approximate  $d = .32$ ), PRF-U ( $d = .65$ ), PRF-A ( $d = .81$ ), fluency rate ( $d = .58$ ), and comprehension ( $d = .51$ ). The treatment effect on word reading accuracy gains detected in our direct effects model was now accounted for by the other variables (recall that the treatment group was significantly lower than the control group on WR pretest). Moreover, although direct treatment effects on word reading efficiency and comprehension were not detected in our prior direct effects models, unique positive treatment effects were found in the presence of OTR, RAN, WR, and interactions.

**Unique OTR effects.** Model results revealed that OTR had small but reliable unique effects on students' gains in word reading accuracy ( $d = .30$ ), word reading efficiency ( $d = .33$ ), PRF-U ( $d = .33$ ), and fluency rate ( $d = .36$ ). (To compute the effect sizes, we contrasted model-predicted student gains for 1  $SD$  above the mean, OTR = 1, with student gains at the average, OTR = 0.) For example, students whose teachers spent 1  $SD$  more on OTR (approximately 22.8 min; see Table 2) were estimated to have a 1.3-point advantage on word reading accuracy gain over those whose teachers spent less time (5.2 min), holding other variables constant.

**Unique pretest effects.** Results showed that RAN was uniquely predictive of higher gains in word reading accuracy ( $d = .20$ ), both PRF measures ( $d = .38$  and  $.39$  for PRF-U and PRF-A, respectively), and fluency rate ( $d = .26$ ). WR was also uniquely predictive: Students with higher WR were predicted to have smaller word reading accuracy gains ( $d = -.49$ ) but higher gains in word reading efficiency ( $d = .23$ ), PRF-U ( $d = .27$ ), and fluency rate ( $d = .36$ ).

**Interactions.** There were complex interactions present across all gain measures except PRF-A. Although there were no signif-

icant two-way Group  $\times$  OTR interactions, there were three significant complex interactions involving group, OTR, and pretest measures (for PRF-U, there was a significant Group  $\times$  RAN  $\times$  OTR interaction; for comprehension, there was a significant Group  $\times$  WR  $\times$  OTR interaction; for both, there were significant four-way interactions). Significant interactions between group and RAN (for gains on PRF-U and comprehension) and between group and WR (for gains on word reading accuracy and efficiency, PRF-U, and fluency rate) were evident, as were interactions between RAN and OTR (for gains on word reading accuracy, both PRF measures, and comprehension) and RAN and WR (for gains on word reading accuracy and efficiency, and comprehension). In general, these interactions indicate that the benefits of a repeated reading intervention and/or increased classroom OTR for second- and third-grade students is dependent on students' initial RAN and WR skills.

To achieve better insight about these interactions, we created plots (see Figures 1–3) using model-predicted parameter estimates (see Table 4) in concert with selected values of the predictors as follows: Group was 1 = treatment,  $-1$  = control; OTR was  $-1$  = 1  $SD$  below the mean (5.2 min of the literacy block), 0 = mean (14.0 min of the literacy block), and 1 = 1  $SD$  above the mean (22.8 min of the literacy block); pretest RAN was  $-1$  = 1  $SD$  below the mean (10th percentile based on norms), 0 = mean (25th percentile based on norms), and 1 = 1  $SD$  above the mean (50th percentile based on norms); and pretest WR (all values observed in the sample, from 76 to 114). Visual inspection revealed a few remarkable patterns. First, OTR practice—whether in the classroom (OTR) or in paired tutoring (treatment)—appeared to benefit students who were below (approximately) the 50th percentile on fall WR (irrespective of pretest RAN) on gains in word reading accuracy and word reading efficiency. This pattern was similar for gains on both PRF-U and fluency rate measures, with one exception. Students with very low RAN (bottom 10th percentile) and low WR appeared to have higher gains if they received both treatment and high OTR or received no treatment with low OTR (perhaps more classroom time allocated to word study development). Finally, inspection of Figure 3 (right side) illustrates the complexity of individual differences in comprehension gains: Students with very low to moderately low RAN (10th to 25th percentile) appeared, overall, to benefit from paired tutoring over no tutoring; that said, treatment students did not appear to benefit from added OTR in terms of comprehension gains, whereas control students did appear to benefit from added OTR. Taken together, these findings suggest that students with lower RAN will have the highest comprehension gains if only a moderate amount of OTR practice is employed. Nevertheless, students with average RAN did not appear to be differentiated by group in terms of comprehension; instead, it appeared that less OTR had positive benefits for these students.

### Discussion

The present study evaluated the direct and indirect effects of a supplemental, paraeducator-implemented repeated reading intervention (*Quick Reads*) with incidental word-level instruction for second and third graders with low fluency skill. Results show clearly that students benefited from this intervention in terms of word reading and fluency gains. Specifically, our models that

Note. *N* = 46 teachers and 141 students (*n* = 71 treatment, *n* = 70 control). Degrees of freedom for conditional mean gains is 44; *df* = 125 otherwise. OTR = standardized (grand-mean centered) average midyear minutes spent on oral text reading; RAN = standardized (grand-mean centered) pretest Letter Naming standard score from the Rapid Automatized Naming/Rapid Alternating Stimulus tests. WR accuracy (as predictor) = standardized (grand-mean centered) pretest Word Identification standard score from the Woodcock Reading Mastery Test—Revised/Normative Update (WRMT-R/NU). For each outcome: pretest-posttest gains are analyzed; WR accuracy = WRMT-R/NU Word Identification; WR efficiency = Sight Word subtest from the Test of Word Reading Efficiency; PRF-U and PRF-A = words-correct-per-minute performance on uniform and alternate passages, respectively, from the Oral Reading Fluency subtest from the Dynamic Indicators of Basic Early Literacy Skills; Fluency rate = Rate subtest from the Gray Oral Reading Tests-4 (GORT); Comprehension = GORT Comprehension subtest.

<sup>a</sup> 1 = treatment; -1 = control.

\* *p* < .05. \*\* *p* < .01. \*\*\* *p* < .001.

Figure 1. Model-predicted word reading (WR) accuracy and efficiency gains by pretest WR accuracy, paneled by three levels of rapid automatized naming (RAN): 10th percentile (PR; top), 25th PR (middle), and 50th PR (bottom). Lines represent experimental group and amount of classroom oral text reading (OTR).

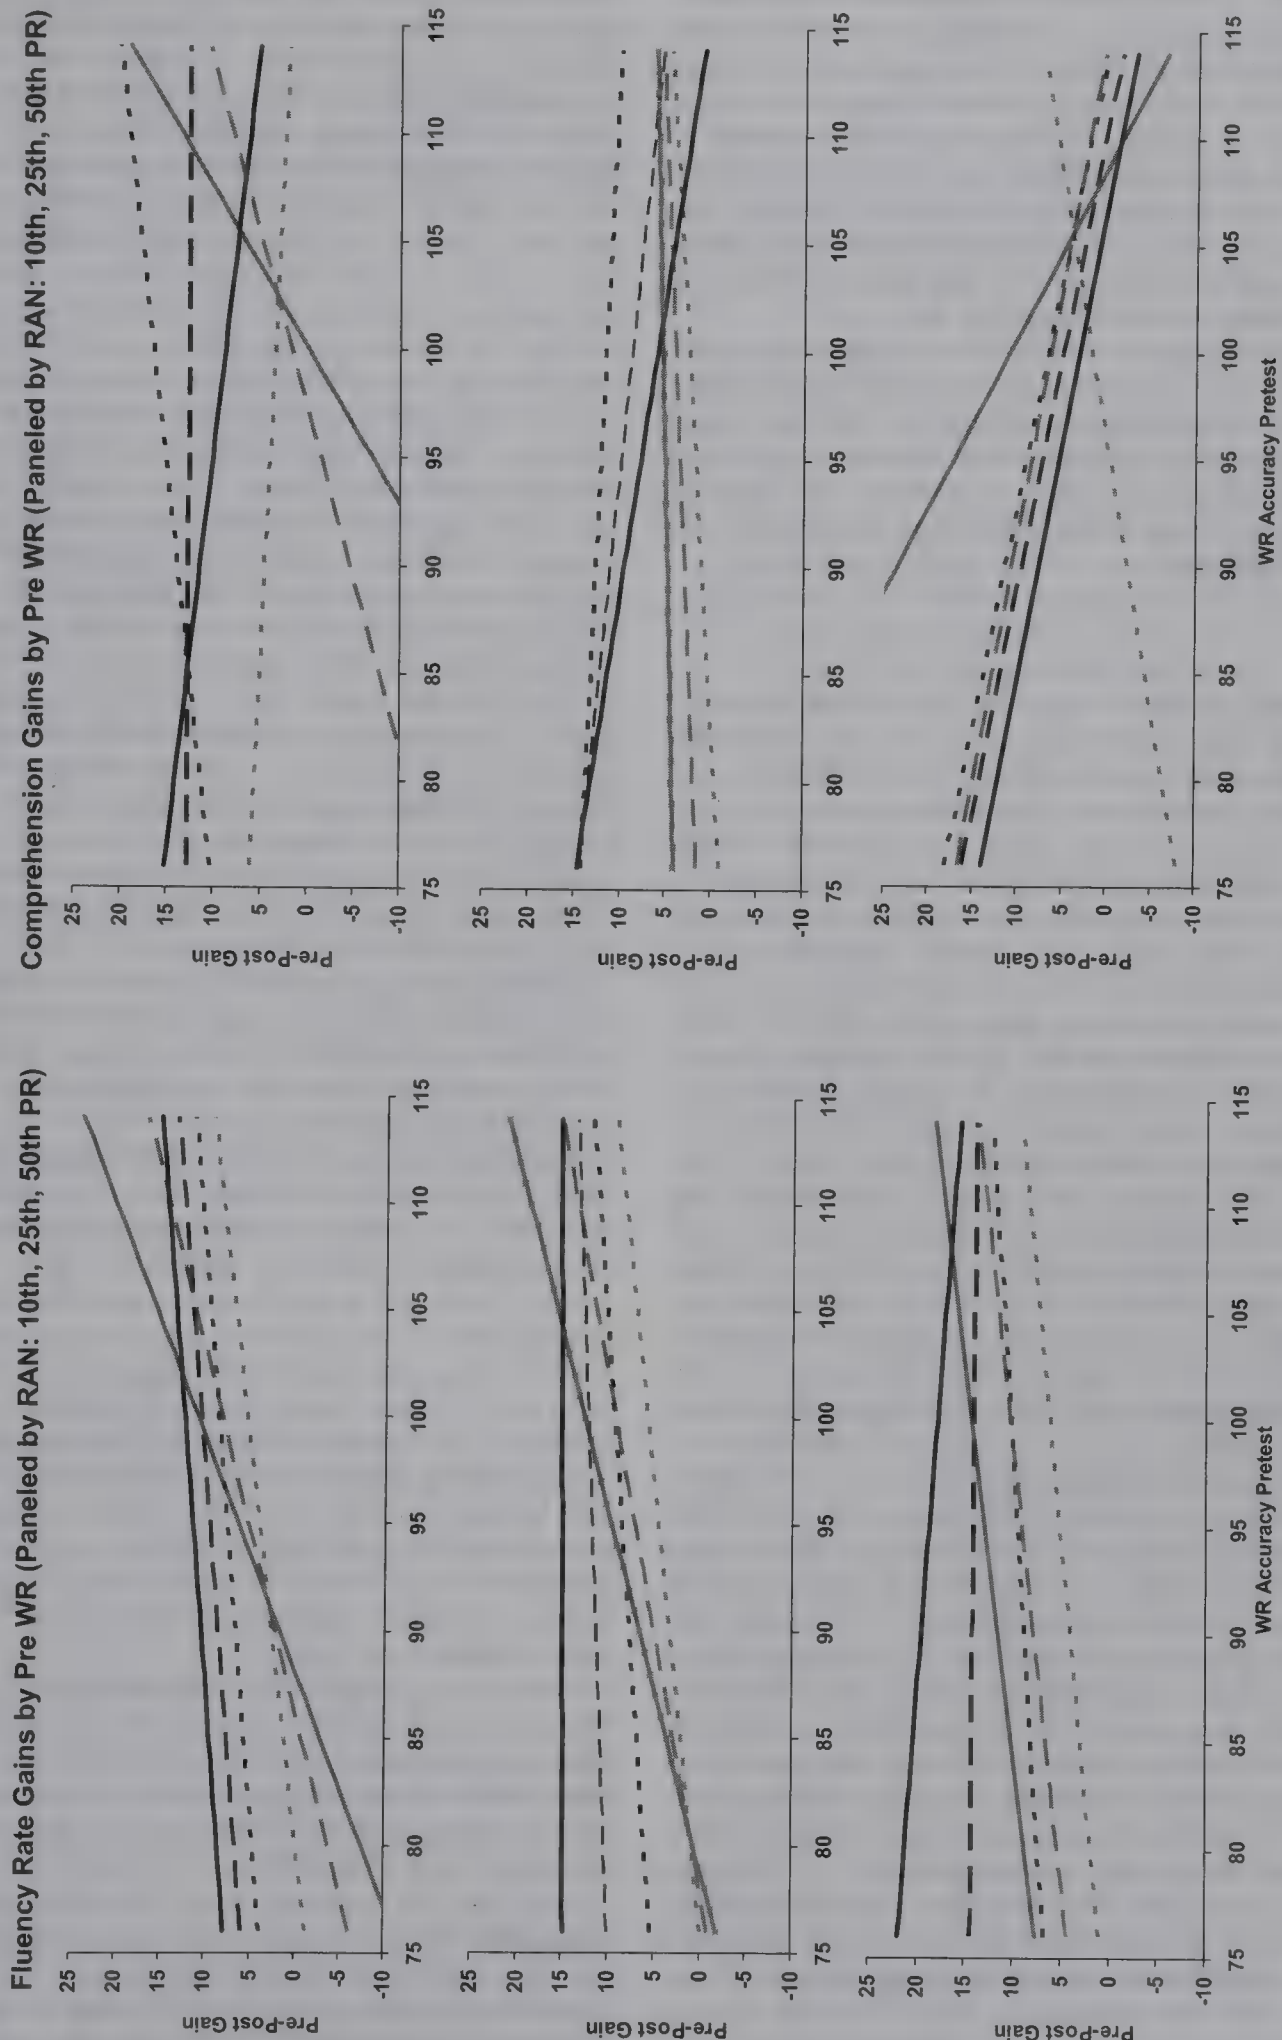

Figure 3. Model-predicted fluency rate and comprehension gains by pretest word reading (WR) accuracy, paneled by three levels of rapid automatized naming (RAN): 10th percentile (PR; top), 25th PR (middle), and 50th PR (bottom). Lines represent experimental group and amount of classroom oral text reading (OTR).

tested for direct treatment effects indicated that tutored students had significantly higher pretest–posttest gains in word reading accuracy and fluency. Dividing the treatment group's average wcpm gains (see Table 3) by 15 weeks of intervention yields average weekly gains of 2.9 and 2.1 wcpm for PRF–U and PRF–A, respectively. By both counts, this is well over the 1.1 wcpm/week expected for low to moderately low students in Hasbrouck and Tindal (2006). Nevertheless, the treatment group's mean posttest PRF performance was below the 50th percentile according to all three of our fluency measures (see Table 3).

Of our classroom observations, the characteristic of most interest in this study was the amount of time students spent reading aloud during the literacy block. When classroom OTR time, pretest RAN, and pretest WR were added to our second set of models, significant unique treatment effects were detected for gains on word reading efficiency, fluency, and comprehension, but not word reading accuracy.

### Gains

*Word reading accuracy and efficiency gains.* Children entered this study with fluency performance ranging from the 10th to 60th percentiles according to Hasbrouck and Tindal (2006) norms on two grade-level passages, and in the bottom 10th percentile according to norms on the Rate subtest from the GORT. Verbal efficiency theory (Perfetti, 1992; Perfetti & McCutchen, 1987) suggests that students' beginning word reading skill and naming speed influence the consolidation of specific fluency component skills. The significant, complex interactions observed in our second set of models unmistakably suggest that effects of repeated reading practice on reading subskill gains are dependent on beginning word reading and/or RAN skills. Examination of the findings for word reading accuracy gains (see Table 4) showed that the repeated reading intervention with incidental word-level instruction (treatment) was reliably moderated by pretest WR: Holding the other variables constant, treatment students with lower pretest WR were predicted to have a slightly higher gain in word reading accuracy compared with controls, whereas the opposite was predicted to be true for students with higher pretest WR. Classroom OTR, pretest RAN, and their interaction had unique, positive effects on word reading accuracy gains. This suggests that students with higher RAN who receive more classroom OTR will have a cumulative advantage of approximately 3 points ( $1.33 + 0.89 + 0.75 = 2.97$ ) in gains compared with students with lower RAN who receive lower amounts of classroom OTR, holding all other variables constant. Finally, this outcome was the only one in which pretest WR had a unique negative effect on gains, indicating that students with higher WR pretest had lower word reading accuracy growth. Furthermore, pretest WR interacted negatively with RAN in addition to group, revealing that students with low pretest WR and high RAN had higher gains. Findings for word reading efficiency gains (see Table 4 and Figure 1, right side) were similar to those found for word reading accuracy, although for this outcome treatment had a unique, positive effect and there were no unique RAN effects or interactions between RAN and classroom OTR.

*Fluency gains.* Reading fluency rate gains were measured in a raw-score and norm-referenced framework using grade-level reading passages (one uniform passage, PRF–U; and one alternate passage, PRF–A) and the norm-referenced GORT Rate subtest.

For all three measures, treatment students had significantly higher gains than controls, and, similarly, students with higher RAN had higher gains. Except for PRF–A, classroom OTR and pretest WR were positively predictive of fluency gains; however, just like our models for word reading efficiency and accuracy, a significant negative interaction between pretest WR and experimental group was also detected: Treatment students with lower pretest WR were predicted to have higher gains than treatment students with higher pretest WR. Two other findings with respect to fluency gains are noteworthy. First, for both of our PRF passages (PRF–U and PRF–A), the benefits of effects of classroom OTR were positively dependent on pretest RAN: In other words, students with higher RAN had more raw score fluency gains if they were in classrooms with higher amounts of OTR. This interaction is consistent with our findings for word reading accuracy. Second, gains on our uniform passage fluency measure (PRF–U) resulted from reliable complex interactions between all predictors (see Table 4); although several interpretations of the three- and four-way interactions may be used, the predicted values of PRF–U gains illustrated in Figure 2 are remarkably similar to the other fluency measures.

*Comprehension gains.* After controlling for students' pretest levels and oral classroom text reading time, we detected a positive unique effect of treatment on comprehension gains. Nevertheless, this benefit of repeated reading intervention is qualified by several complex interactions among the other predictors in the model, highly similar to those detected for the PRF–U fluency measure. Predicted gain values (illustrated Figure 3, right side) appear to suggest that students with lower levels of RAN (10th or 25th percentiles) had higher gains if they were in the treatment group, and even higher gains, on average, if they were in classrooms that focused less time on OTR. In contrast, students with higher RAN (50th percentile) did not appear well-differentiated by which experimental group they were in.

Verbal efficiency theory (Perfetti, 1992; Perfetti & McCutchen, 1987) incorporates the notion of the autonomous lexicon, a bank of accurate word representations that underlie fluent reading. Findings from this study suggest that if students have lower word reading accuracy skills and an insufficiently encapsulated lexicon, higher RAN permits them to benefit from either type of oral reading practice across word and rate measures. Children with lower RAN and lower word reading accuracy had less fluency or comprehension gains from classroom OTR opportunities alone but were most advantaged by repeated reading instruction. Students' initial higher word reading skill uniquely predicted lower word reading accuracy gains but greater fluency rate gains. The role of word reading skill in explaining growth for students with low levels of reading fluency is consistent with previous studies (Jenkins, Fuchs, van den Broek, Espin, & Deno, 2003; Torgesen et al., 2001).

These findings suggest when particular types of repeated reading will be beneficial. For students performing within the emergent stage of reading fluency, like the second and third graders in this study, there were benefits from rereading the same texts chosen at an instructional level of difficulty. Repeated reading was assisted by trained tutors who provided both a model of fluent reading during two of the rereadings, as well as corrections and feedback during three of the readings. The intervention incorporated features found by others to be effective. These include use of a structured, research-based protocol; inclusion of alphabetic and word-level instruction; and rereading of texts. Although the supplemental

intervention in the present study was not explicitly coordinated with classroom instruction, as others have recommended (Jenkins & Jenkins, 1987; Reisner et al., 1990; Venezky & Jain, 1996; Wasik, 1998a), *Quick Reads* texts are designed to coordinate with grade-level science and social science content and vocabulary. Furthermore, the two-level models in this study suggest that added oral reading practice in the classroom enhances fluency effects of the repeated reading intervention.

### Limitations

Findings from this study should be considered in light of several limitations. First, although the intervention used in this study was primarily characterized as repeated reading, a small portion (up to 5 min) of each of the tutoring sessions included incidental alphabetic instruction and word-level scaffolding. Although most repeated reading interventions described in the literature do not include this feature, the teacher manual suggests that this is an option teachers might use in implementing *Quick Reads*. Second, students entered this study with a wide range of pretest fluency levels that reflected teacher referral patterns; nevertheless, students ranged from the 10th to the 60th percentiles on PRF performance, similar to students served in repeated reading programs (Faulkner & Levy, 1999; Hasbrouck et al., 1999). Third, we observed classroom instruction only twice during the intervention. As others have demonstrated (Connor, Morrison, & Petrella, 2004), dimensions of classroom instruction that our coding system did not capture, such as individual student engagement or quality of instruction (Connor, Son, Hindman, & Morrison, 2005), may have influenced student outcomes. Fourth, our findings on classroom literacy instruction are based on data excluding six teachers (and their students). It is possible that these teachers' refusal to participate reflects a systematic difference in their literacy instruction; however, outcomes of students within these classrooms did not reliably differ from outcomes of students whose teachers were observed. A final limitation of this study is that many variables expected to contribute to comprehension gains were not accounted for in this study, including vocabulary knowledge, strategy skills, and general language skills.

### Instructional Implications

The fluency gains on both the norm-referenced and the PRF-U measure resulting from the supplemental repeated reading intervention were greatest for students with below-grade-level word reading skills. Higher levels of RAN appeared to allow students at this emergent stage of fluency development (Schwanenflugel et al., 2006) to benefit more from treatment, although this type of interaction was only reliably evident for one of our fluency measures (PRF-U). Inspection of the plots in Figures 1–3 suggests that if students enter second or third grade with average or higher word reading skills, a repeated reading intervention is not recommended to boost word reading accuracy or comprehension skills in particular. Students with lower word reading skills at onset, however, will likely benefit from this type of intervention on reading accuracy and fluency rate gains.

Second and third graders entered this study at different levels of component skill fluency. Word reading skills at pretest averaged in the lowest 40th percentile. The pretest range in word reading skills suggested that we add an incidental word-level instruction layer to the

intervention; this instruction, together with the *Quick Reads* text features, may have enabled students with lower word reading skills to make the greatest gains relative to controls across reading outcomes. Gains in fluency and comprehension reflect, to some extent, an interactive compensatory mechanism (Rumelhart, 1977) for RAN and word reading skills. It appears that when bottom-up processing was slow due to both underlying slow RAN and inaccurate decoding, students could not make gains in fluency or comprehension from classroom oral reading practice opportunities. However, either high RAN or stronger word reading skill seems to enable compensatory processing and gains in fluency and comprehension. Students with high word reading pretest made high fluency and comprehension gains despite low RAN, and students with high RAN made comprehension gains despite low word reading. Higher RAN was associated with similar comprehension gains for both treatment and control students with low word reading pretest scores.

Findings support clear benefits from the opportunities students had to engage in oral reading practice during the classroom reading block. When students read aloud, teachers have opportunities to detect student difficulties, including poor prosody, decoding errors, and limited comprehension reflected in dysfluent reading. Teachers can use this information to adjust instruction for individual students and provide effective corrections and scaffolding. Teachers have no access to this information when students engage in silent reading.

The findings also support the benefits of supplemental repeated reading instruction using the *Quick Reads* program. Students with below-grade-level word reading skill made the greatest gains in reading skills due to intervention. As we noted, tutors implemented *Quick Reads* instruction with incidental word-level instruction. We believe that this adaptation is in line with instructional applications recommended in the *Quick Reads* teacher manual and is most appropriate for students who have not yet developed accurate and efficient word reading skills. These students are also most likely to benefit from the text characteristics of the *Quick Reads* program. Students with average or higher word reading accuracy may have benefited most from incidental and more individualized instruction in fluency and comprehension skills during classroom reading instruction.

Tutors in this study were paraeducators, and they implemented the intervention with a high degree of fidelity. There is growing evidence that teaching assistants and tutors can assume important pedagogical roles in early literacy instruction (Al Otaiba, Schatschneider, & Silverman, 2005; Gelzheiser, 2005; Hatcher et al., 2006), with corresponding calls for increased training and utilization of these individuals (Callas, 2001; Savage & Carless, 2005). Research is warranted on the specific instruction and curricula these individuals can implement most effectively.

This study specifically addressed limitations in previous research on repeated reading interventions. First, students were randomly assigned to conditions. Second, we considered multiple outcomes, including word reading accuracy and efficiency as well as fluency rate and comprehension outcomes. Third, because this was an efficacy trial, the intervention was implemented with a high degree of fidelity by paraeducators who were potential typical end users, and in school settings that reflected routine practice conditions. Fourth, the 15-week intervention was considerably more intense than the repeated reading interventions described in many previous studies. Fifth, the particular repeated reading intervention, *Quick Reads*, is unusually well specified in terms of text features and

reading procedures often hypothesized to influence fluency outcomes. Finally, we conducted classroom observations to measure and account for the influence of classroom literacy instruction similar to that of the intervention on student outcomes. Specifically, we estimated OTR practice that students received in the classroom.

In summary, findings indicate that student word reading and RAN skills should be taken into account when identifying students for placement in a repeated reading intervention. The findings also underscore the value of classroom oral reading practice for students with low to moderate reading fluency and the importance of accounting for the role of classroom reading instruction experienced by children in supplemental reading interventions. Finally, findings support the difficulty described by others (Torgesen et al., 2001) of completely or quickly remediating poor fluency. This difficulty is not limited only to older students with cumulative fluency lags, as in this study we were unable to bring second- and third-grade students in the intervention up to grade-level fluency. Young students whose fluency is already constrained by limited word-level skills may require significantly greater amounts of repeated reading practice than employed in this intervention, as well as more intensive instruction to develop word-level proficiency.

# On Warm Conceptual Change: The Interplay of Text, Epistemological Beliefs, and Topic Interest

Lucia Mason, Monica Gava, and Angela Boldrin  
University of Padua

The aim of this study was to go further than considering only cognitive factors to extend the understanding of the complex, dynamic underlying knowledge revision processes. Fifth graders were assigned to 2 reading conditions. Participants in 1 condition read a refutational text about light, whereas participants in the other read a traditional text. Within each reading condition, students had more or less advanced beliefs about scientific knowledge (complex and evolving vs. simple and certain), as well as high or low topic interest. Overall findings from pretest to immediate and delayed posttests showed that knowledge revision was affected by several interactions among the variables examined. Students who attained the highest scores at both the immediate and delayed posttests were those who had read the refutational text and had high topic interest, as well as more advanced beliefs about scientific knowledge. In particular, the refutational text was more powerful in prompting a restructuring of alternative conceptions about 2 of the 3 light phenomena examined. In addition, students preferred the innovative text to the traditional textbook text.

**Keywords:** conceptual change, refutational text, epistemological beliefs, interest

In their classic article, Pintrich, Marx, and Boyle (1993) called for *hot conceptual change*, that is, to go further than considering only cognitive factors and to also take into account the affective, motivational, and social/contextual aspects that may affect knowledge revision. As described by Sinatra (2005), this article inspired a *warming trend* in theory and research on conceptual change. New models and empirical studies began emphasizing motivation as crucial to knowledge restructuring. Our study examined two learner factors considered by Pintrich and associates (Pintrich, 1999; Pintrich, Marx, & Boyle, 1993) as possible motivational resources for conceptual change: epistemological beliefs and interest. The study also examined an instructional factor, the type of text to be learned to integrate new knowledge into existing conceptual structures. Our study therefore focused on the interplay between instructional and learner variables to extend the understanding of the complex dynamics underlying the process of conceptual change. The investigation of this interplay is in line with most recent research in this field, which highlights the intricacy of the change process and the delicate interactions of multiple factors that shape that process (Alexander & Sinatra, 2007; Murphy & Mason, 2006; Sinatra & Mason, in press). In previous research, these three variables have been examined separately (e.g., Hynd,

2003; Qian & Alvermann, 2000; Qian & Pan, 2002; Venville & Treagust, 1998) or in pairs, for example, refutational text and epistemological beliefs (Mason & Gava, 2007) or epistemological beliefs and interest (Mason & Boscolo, 2004).

## Refutational Text

Most learning required in the school context occurs through successful text reading. Text is still the main medium for acquiring disciplinary knowledge. It is widely accepted that the text comprehension process implies constructing a mental representation of the text or situation model based on integrating information found in the text with the reader's prior knowledge (Chan, Burtis, Scardamalia, & Bereiter, 1992; Goldman & Bisanz, 2002; Kintsch, 1986). This integration often requires readers to restructure their preconceptions if they are incompatible with the new knowledge to be learned. The role of text in promoting conceptual change may therefore be crucial. Science texts are expository texts that provide information about phenomena usually by presenting a series of facts. There is evidence that the structure of standard science texts may induce only superficial processing and may fail to sustain meaningful learning, especially when the reader has alternative conceptions about the topic (e.g., Chambliss, 2002). In the study reported here, we examined the role of the refutational text, which has been found to be effective in science learning because of its structure. A refutational text is a text that acknowledges students' alternative conceptions about a topic, directly refutes them, and introduces scientific conceptions as viable alternatives (Alvermann & Hague, 1989; Hynd, McWhorter, Phares, & Suttles, 1994; Hynd, Qian, Ridgeway, & Pickle, 1991).

The first studies showing the power of a refutational text structure were carried out in the 1980s. For example, Maria and MacGinitie (1987) revealed that fifth and sixth graders more easily abandoned their misconceptions about common topics when they

read a refutational text than when they read an expository one that simply presented the new information. Since then, the effectiveness of refutational texts in knowledge-restructuring processes has been revealed in several studies (e.g., Guzzetti, Snyder, Glass, & Gamas, 1993; Guzzetti, Williams, Skeels, & Wu, 1997; Qian & Pan, 2002). More specifically, the superiority of a refutational text, compared with a traditional one, has been documented in the learning of physics (Hynd, 1998; Wang & Andre, 1991) and biology concepts (Mikkilä-Erdmann, 2002) in students of elementary school (Diakidoy, Kendeou, & Ioannides, 2003), middle school (Mason & Gava, 2007), high school, and college (Alvermann & Hynd, 1989; Chambers & Andre, 1997), as well as in the change of preservice teachers' beliefs about mathematics teaching and learning (Gregoire Gill, Ashton, & Algina, 2004). Through interviews, it also emerged that students prefer refutational texts over other types of science texts about the same topic (e.g., Guzzetti, Hynd, Skeels, & Williams, 1995; Hynd, 2003).

Why are refutational texts powerful? According to Hynd (2003), three explanations can account for the benefits of refutational texts. The first refers to the four conditions for conceptual change, highlighted in the well-known article by Posner, Strike, Hewson, and Gertzog (1982). In other words, refutational texts elicit dissatisfaction with the reader's current conceptions, explain the scientific concept clearly and in depth, make it plausible through believable examples, and finally show the usefulness of the new concept. The second explanation for the power of refutational texts refers to the necessary characteristics of any anomalous data that increase the likelihood that they be accepted as valid. That is, to be accepted, data must be credible, unambiguous, and in multiple forms (Chinn & Brewer, 1993, 1998). The third explanation, grounded in social psychology literature, refers to readers' central, and not peripheral, text information processing, activated by refutational texts. A fourth explanation can be added, regarding the possibility that refutational texts enhance situational interest. As discussed later, this type of interest is triggered by specific text characteristics, for example, concreteness and ease of comprehension (e.g., Schraw, Bruning, & Svoboda, 1995), and may enhance learning.

### Epistemological Beliefs

When confronted with new knowledge to be learned, students do not just activate their preexisting knowledge about the topic but also activate their beliefs about knowledge itself. Beliefs about knowledge and knowing, namely epistemological beliefs, are individuals' representations about the nature, organization, and source of knowledge, its truth value, and the justification criteria of assertions (Hofer & Pintrich, 1997, 2002). In the work of scholars interested in developmental aspects, epistemological thinking has been considered a cognitive structure comprising coherent and integrated representations, which characterizes a level or stage of cognitive development. A shared developmental sequence can be identified in their models (e.g., King & Kitchener, 1994; Kuhn, 2000; Kuhn, Cheney, & Weinstock, 2000). Substantially, the shift indicated is from belief in knowledge as absolute, simple, certain, and transmitted by authorities, to belief in knowledge as relative, idiosyncratic, and uncertain, to belief in knowledge as complex, evolving, rationally evaluated, and derived from reason.

In the work of scholars interested in the relationship between epistemological beliefs and learning processes, the construct of epistemological beliefs has been conceived as multidimensional. Agreement about four epistemological dimensions can be identified in the literature (e.g., Hofer, 2000, 2004; Schommer, 1990, 1994; Schommer-Aikins, 2002; Wood & Kardash, 2002). Two dimensions regard the nature of knowledge. The first concerns beliefs about the simplicity versus the complexity of knowledge: the degree to which knowledge is conceived as compartmentalized or interrelated, ranging from knowledge as made up of discrete and simple facts to knowledge as complex and interrelated concepts. The second dimension concerns beliefs about the certainty versus the complexity of knowledge: the degree to which knowledge is conceived as stable or changing, ranging from absolute to tentative and evolving knowledge. Two belief dimensions regard the nature of knowing. The first concerns the source of knowledge: the relationship between knower and known, ranging from the belief that knowledge resides outside the self and is transmitted to the belief that knowledge is constructed by the self. The second dimension concerns the justification of knowledge: what makes a sufficient knowledge claim, ranging from the belief in observation or authority as a source to the belief in the use of rules of inquiry and evaluation of expertise. According to some scholars (e.g., Schommer, 1990), these four epistemological dimensions may be independent, and an individual may have more sophisticated beliefs in one of them and less sophisticated beliefs in another. According to some other scholars (e.g., Hofer, 2000), beliefs about knowledge and knowing are not a set of independent ideas, but rather are a coherent integration of compatible perspectives, that is, theories, whose core is comprised of the four dimensions. Although divergences exist in their conceptualization of epistemological beliefs (see also Hammer & Elby, 2002), overall it can be said that scholars substantially agree on the essential steps in the development of representations about knowledge and knowing.

In agreement with Bendixen (2002), who examined the perception, description, and solution of epistemic doubt in undergraduate students, it should also be pointed out that epistemological beliefs are not *cold cognition*. The affective nature of deeply held beliefs is an important aspect to be taken into consideration. The recognition of uncertainty and complexity of knowledge can be worrisome for students. Affective consequences (i.e., feelings of fear, confusion, or anxiety) may also derive from abandoning the security of absolutistic stances (Hofer, 2005).

A number of empirical studies have been carried out concerning the relationship between epistemological beliefs and conceptual change learning. To our knowledge, almost all studies are based on the conceptualization of personal epistemology as a multidimensional construct, which has been measured through questionnaires made up of items to be rated on a Likert-type scale. More specifically, original or reduced versions of Schommer's (1990) Epistemological Questionnaire have been used. It should be pointed out, however, that in many cases, the focus has been on two of the four dimensions underlying this instrument, that is, beliefs in the simplicity versus the complexity of knowledge and beliefs in the certainty versus the uncertainty of knowledge. Thus, the label *epistemological beliefs* may refer only to beliefs about the structure (simplicity vs. complexity) and stability (certain vs. evolving) of knowledge. In reviewing previous studies, we specify which dimensions of beliefs are examined.

Qian and Alvermann (1995) found that after reading a text on Newtonian theory, high school students who believed more in the simplicity and certainty of knowledge were less likely to abandon naïve conceptions of motion. In contrast, students who believed more in the complexity and instability of knowledge produced greater change in their conceptual structures. Windschitl and Andre (1998) documented that college students with beliefs in knowledge as complex, evolving, and gradually learned changed their initial conceptions about the cardiovascular system more in the constructivist than in the traditional learning environment. Sinatra and colleagues (Sinatra, Southerland, McConaughy, & Demastes, 2003; Southerland & Sinatra, 2003) investigated not only epistemological beliefs but also cognitive dispositions—such as the disposition to engage in effortful, open-minded thinking and not to identify too strongly with one's beliefs—in relation to the acceptance of human evolution. College students who believed more in complex and uncertain knowledge and had a greater disposition toward critical and open-minded thinking were more likely to accept human evolution than students with less advanced epistemological beliefs who were less disposed toward critical and flexible thinking. Kardash and Scholes (1996) also found that the more college students were disposed to cognitive involvement, the more they wrote paragraphs taking into account the inconclusive nature of controversial evidence presented in the dual-positional text that they read. In addition, the more they believed in uncertain knowledge, the less radical were their initial beliefs about the controversy. In line with Chinn and associates' (Chinn & Brewer, 1993; Chinn & Malhotra, 2002) analysis of the factors that facilitate or constrain theory change, Mason (2000) documented that beliefs about the certainty of knowledge were related to the acceptance of anomalous data, as well as to theory change about a controversial scientific topic. Middle school students who believed in the changing nature of knowledge were more likely to recognize the validity of evidence conflicting with their prior conceptions and, consequently, to change them.

More recently, Nussbaum, Sinatra, and Poliquin (2005) found that college students with evaluativist positions about the physical world—those who believed that different knowledge claims are legitimate but can be rationally compared and evaluated to judge which is more sustainable—showed a greater decline in misconceptions about falling objects than students with absolutist positions. Stathopoulou and Vosniadou (in press) also indicated that 10th graders' physics-related beliefs about the structure, stability, source, and attainability of knowledge were necessary, although insufficient, for a conceptual understanding of physics.

The relationship between epistemological beliefs and text (refutational vs. traditional) reading in conceptual change processes has also been studied (Mason & Gava, 2007). Eighth graders who read a refutational text and believed more in complex and uncertain knowledge changed their misconceptions about biological evolution more than those who read a traditional text.

Why do more sophisticated epistemological beliefs act as a resource whereas less sophisticated beliefs act as a constraint in conceptual change? An account based on the notion of intentionality can be proposed (Sinatra & Pintrich, 2003a). As posited by Sinatra and Pintrich (2003b), a key to intentionality in knowledge revision processes is that "students must have a deliberate *goal orientation* . . . to learn and understand the material" (p. 5). By appealing to this notion, Mason (2003) proposed that beliefs about

knowledge may or may not guide students toward the goal of learning through knowledge revision. In this case, intentionality requires that students recognize that what they already know does not match a new conception or that they perceive the potential of new information. Only beliefs in complex, hypothetical, and evolving knowledge are conducive to that recognition. Once they have recognized that, students must invest their effort in solving problems concerning the current state of their own understanding in order to intentionally produce changes in knowledge (Mason, in press). Systematic or deep processing of the content (Kardash & Howell, 2000) seems to mediate the role of epistemological beliefs in intentional conceptual change. Gregoire Gill, Ashton, and Algina (2004) have documented that preservice teachers who held beliefs in knowledge as simple and certain were less likely to engage in deep thinking about the content of a text and, in turn, were less likely to change their beliefs about mathematics teaching and learning. Epistemological beliefs may also have a direct effect because the conviction that knowledge is simple and certain may lead a student to focus only on items of factual knowledge (Stathopoulou & Vosniadou, in press).

### Topic Interest

We examined a third variable, interest, that may play a role in conceptual change learning. Neglected for decades, this motivational variable has been reconsidered since the mid-1980s (Hidi & Baird, 1986). Conceptualized in terms of both a psychological state and an individual predisposition, interest has been investigated for its influence on cognitive and affective functioning (Renninger, 1990, 2000; Renninger, Ewen, & Lasher, 2002; Renninger & Wozniak, 1985; Schiefele, 1991, 1996). Studies on the relationship between interest and learning have mainly been conducted in the light of the useful distinction between individual and situational interest (Alexander, 1997, 1998; Hidi, 2001; Renninger, 1992; Renninger, Hidi, & Krapp, 1992; Tobias, 1994). Individual interest is distinct from other related motivational constructs and is a relatively stable evaluative orientation toward certain classes of objects, ideas, or events, which is reflected in a relatively enduring predisposition to re-engage with them over time. Situational interest is generated by certain conditions and/or environmental stimuli, such as novelty and intensity. Typically, textual features can elicit a form of interest, called situational interest, that refers to short-term involvement with a class of objects (Renninger, 2000). It has been maintained, however, that situational interest may evolve into individual interest (Hidi & Anderson, 1992), as well as that well-developed individual interest needs to be sustained and challenged (Renninger & Hidi, 2002).

Of special note is research on the development and deepening of interest in subject matter (e.g., Lipstein & Renninger, 2006). A four-phase model has recently been proposed, which relates the constructs of individual interest and situational interest (Hidi & Renninger, 2006). This model includes the following: triggered situational interest, maintained situational interest, emerging individual interest, and well-developed individual interest. Each phase includes both affective and cognitive factors, that is, a certain amount of affect, knowledge, and value. It has been documented that continued (individual) interest in a discipline is related to types of achievement goals. College students' mastery goals pre-

dicted their interest in an introductory psychology course (Harackiewicz, Barron, Tauer, Carter, & Elliot, 2000).

In the current study, we examined topic interest, a motivational construct used in both the individual and situational literatures "to refer to the likelihood of attending to particular subject content . . . or positive feelings for content" (Renninger, 2000, p. 376). We examined topic interest, which is distinct from both individual and situational interest, for two main reasons. First, it is particularly relevant to educators (Ainley, Hidi, & Berndorff, 2002), because this type of interest is most likely evoked when students are introduced to topics in school contexts that they are asked to learn about. Second, for a study focused on changing conceptions about specific scientific phenomena, it was more appropriate to take into account students' degree of interest in the specific topic to be learned about, in addition to their prior knowledge of it.

It is worth noting that topic interest can be considered, to some extent, both individual and situational (Renninger, 2000). Indeed, topic interest can be an expression of individual interest in a specific subject matter, for example, science. At the same time, it can be an expression of situational interest in that it is stimulated by a specific content. Therefore, most topics have both individual and situational sources that contribute to the measured topic interest (Ainley, Hidi, & Berndorff, 2002), especially in young learners, where the former may not be well developed. In the current study, we do conceptually acknowledge that individual interest in science, as well as interest elicited by words or sentences presenting the topic of light, would contribute to the measured topic interest. Nevertheless, topic interest can be conceived as a motivational variable distinct from both individual and situational interests. In addition, although it relates to situational aspects, topic interest can be included as a personal variable, as has been done in most previous investigations. In the current study, it has been considered as a learner variable together with selected relevant dimensions of epistemological beliefs.

Two aspects of topic interest have been distinguished (Krapp, 1999; Schiefele, 1996) and have been taken into account in the study reported here: feeling-related and value-related valences. Feeling-related valences refer to the feelings, for instance, stimulation and involvement, associated with a topic. Value-related valences refer to the attribution of personal significance to a topic. With regard to Hidi and Renninger's (2006) model of interest development, it can be said that topic interest may be an expression of each of the four phases, depending on the contribution of its sources and the degree of cumulative and progressive development. If situational components prevail, one of the two earlier phases is involved, especially in terms of affect or liking and focused attention. If the individual components prevail, one of the later phases is involved, implying not only positive feelings but also stored knowledge and value and repeated engagement.

Although not focused on the change in knowledge, several studies have indicated that topic interest positively influences learning from text. Alexander, Kulikowich, and Schulze (1994) found that college students' topic knowledge and interest significantly predicted comprehension of a technical text on physics. Schiefele (1996) showed that senior high school students with high interest in the topics of prehistoric people and television developed a deeper text comprehension than readers with low interest, regardless of level of prior knowledge. Similarly, in a study by Schiefele and Krapp (1996), topic interest in communication sig-

nificantly affected recall of idea units, elaborations, and main ideas regardless of preexisting knowledge. In Alexander and Murphy's (1998) study, strong interest in concepts such as memory, problem solving, and learned helplessness, as well as willingness to pursue understanding, differentiated highly successful from less successful college students. Boscolo and Mason (2003) found that when high school students' topic interest in global warming was high, it could help their understanding of a text at the superficial level, and also at deeper levels, if associated with high topic knowledge. Ainley, Hidi, and Berndorff (2002) examined whether and how eighth and ninth graders' individual and situational interest contributed to their interest in and learning about different topics, such as body image and X rays. They combined both self-reported measures and online, dynamic measures of affective and cognitive reactions to the reading of science and popular culture texts, through the computer program *Between the Lines*. Topic interest was the outcome of both individual and situational interest factors, which operated in combination or separately. In addition, topic interest was related to affective responses. These were related to persistence that, in turn, was related to learning.

Very few studies have examined the relationship between interest, in either form, and conceptual change, and those that have have revealed that interest may not always be beneficial to conceptual change. In a study of high school students' understanding of genetics, Venville and Treagust (1998) reported some contradictory data. Students interested in the topic produced either high or very low levels of conceptual change. However, students' high interest was in human heredity and not in the microscopic aspects of genetics to be learned. Murphy and Alexander (2004) found that college students with high topic interest were less likely to alter their beliefs. The high correlation between interest and prior knowledge, and the fact that high knowledge often means more resistance to change, could be the cause of the lack of change. As pointed out by Dole and Sinatra (1998), interest could make knowledge revision more difficult if associated with high knowledge. In light of differences in the phases of interest development (Hidi & Renninger, 2006), it is more likely that a well-developed interest acts as a barrier to conceptual change when related to highly developed alternative conceptions.

The positive effect of interest in conceptual change processes has been documented by Andre and Windschitl (2003). They found that college students' interest in learning about electricity affected conceptual change indirectly, through experience that correlated with it, and also directly, independently of its influence on experience. The relationship between topic interest and epistemological understanding has also been examined in high school students' interpretation of a controversy (Mason & Boscolo, 2004). No significant interaction emerged between the two examined variables, although both played a role as single factors.

Why does a high degree of topic interest act as a resource, whereas a low degree may act as a constraint in conceptual change learning? The beneficial effect on interest can be explained by reference to an energizing role in cognitive processing, because it stimulates attentional arousal, positive emotional reactions, effort, and willingness to persist in the task, as documented empirically (e.g., Ainley, Hidi, & Berndorff, 2002) and underlined theoretically (e.g., Alexander, 1998; Hidi, 1990; Renninger, 2000). High interest therefore sustains deep cognitive processing, which is

beneficial to knowledge revision and requires engagement in deep thinking about the content to be learned.

### Research Questions and Hypotheses

To extend current research on conceptual change, we focused on the complex dynamics underlying the process. The aim of this study was to investigate how the text type to be learned and students' epistemological beliefs and topic interest affect revision of their conceptions about a topic. All three variables—each of which can contribute to stimulate and sustain active involvement and deep processing—and their possible relationships in knowledge-restructuring processes were the focus of the study. The variable of students' reading comprehension ability was also considered as a covariate in the statistical analyses. Because the students made up regular heterogeneous classes, their reading ability varied. We chose the topic of light, first because it is a topic central to the Italian science curriculum for the fifth grade, and it had not already been dealt with in the classroom. Second, the students had very low prior scientific knowledge of the topic, and this allowed a better examination of how the chosen variables contributed to new learning.

In particular, the purpose of the study was to examine the following questions:

1. Was students' text retention at the immediate and delayed posttests affected by text type, beliefs about the certainty and development of scientific knowledge, topic interest, and/or their interactions?
2. Was students' overall conceptual change, as reflected by changes in their explanations about light phenomena from pretest to immediate and delayed tests, affected by text type, epistemological beliefs, topic interest, and/or their interactions? In addition, did these factors affect, to the same extent, knowledge restructuring of each of three phenomena about light?
3. Did students prefer a refutational text to a traditional textbook text?

For the first research question, we hypothesized that no significant differences would emerge between participants for the retention of factual information in relation to epistemological beliefs, topic interest, and text type. Because the refutational and traditional texts did not differ in terms of information, participants would retain the same content in the two reading conditions. In addition, as emerged in a previous study (Mason & Gava, 2007), epistemological beliefs would not affect a shallow level of text understanding, which does not require the revision of prior knowledge. Finally, topic interest also would not differentiate text retention because it does not imply deep cognitive processing, which is sustained by the motivational variable.

For the second research question, we hypothesized overall that text type, beliefs about the nature and stability of scientific knowledge, and topic interest would make a difference at the level of deeper text understanding immediately after reading the text and at a delayed posttest. This is the situation model level in Kintsch's (1998) terms; that is, the reader's prior knowledge is integrated with information from the text, which reflects students' conceptual

change. Only when the text information becomes part of the reader's knowledge as it integrates with it, can this information be used in new situations. We hypothesized that the text type would affect students' conceptual change overall. By directly stating and challenging students' alternative conceptions, a refutational text, more than a traditional text, would create or refine students' metacognitive awareness about their own representations and scientific ones, an essential condition for conceptual change (Vosniadou, 2003; Wiser & Amin, 2001). This would increase the likelihood that the former are perceived as limited and the latter as more powerful. We also hypothesized that students with more advanced epistemological beliefs (scientific knowledge as uncertain and changing) would change their alternative conceptions more than those with less advanced epistemological beliefs (scientific knowledge as certain and stable) and that these changes would be persistent.<sup>1</sup> Participants with more advanced epistemological beliefs would be helped in perceiving knowledge problems in their conceptual structures and working toward solving them. Finally, we hypothesized that topic interest would affect knowledge revision overall because this motivational variable would stimulate attentional arousal and deep processing.

For the second research question, we also expected that an interaction among the three variables would emerge. Refutational text reading, more advanced beliefs about the nature of scientific knowledge, and higher topic interest would be a powerful combination of the instructional and personal variables. On the contrary, traditional text reading, less advanced epistemological beliefs, and low interest would lead to a lower performance.

On the basis of the literature, for the third research question we hypothesized that students would prefer a refutational text, which states and challenges their conceptions, to a traditional text, because it is perceived as easier and more helpful in understanding scientific concepts (Guzzetti et al., 1995).

### Method

#### Participants

Initially, the participants involved were 120 fifth graders attending five classes in three public elementary schools in a province of north eastern Italy. All were Caucasian native speakers of Italian and shared a homogeneous middle class social background. Eight of these students were found to have reading difficulties (described later) on administration of a standardized reading comprehension text. In agreement with their teachers, they took part in the study, but their production was not considered in statistical analyses. In addition, a further 6 students were not present at either the pretest or the immediate posttest. There were therefore 106 participants

<sup>1</sup> In the epistemological beliefs literature, terms such as *naïve* and *sophisticated* or *less advanced* and *more advanced* are used. We retain them for reasons of clarity and not to attribute any unfortunate connotation to the terms. In accordance with Schommer-Aikins (2002), we think that when an individual holds sophisticated beliefs, it means that he or she believes mostly in complex and tentative knowledge. However, at the same time, the individual may believe that there is knowledge that is stable and/or isolated. What differentiates an advanced epistemological thinker from a less advanced one is that the belief in certain and simple knowledge is predominant in the latter and is the exception in the former.

who provided data for both the pretest and the immediate posttest. Of these 106 students, 12 were absent on the day of the delayed posttest. Therefore, 94 participants completed the pretest, the immediate posttest, and the delayed posttest (48 girls and 46 boys).

Each class was randomly assigned to one of two reading conditions: a refutational text about light ( $n = 51$ ; 24 girls and 27 boys, including pretest and immediate and delayed posttests) and a traditional text about the same topic ( $n = 43$ ; 24 girls and 19 boys, including pretest and immediate and delayed posttests).

### *Prereading Materials and Tasks*

**Epistemological beliefs.** All but one (Stathopoulou & Vosniadou, in press) of the studies reported in this article used a questionnaire intended to measure general beliefs about knowledge. In this study, we used a more appropriate, science-specific questionnaire, which was an abbreviated version of Conley, Pintrich, Vekiri, and Harrison's (2004) instrument for measuring epistemological beliefs about science in elementary school students. In this way, we tried to overcome the measurement difficulties underlying the use of abstract and domain-general statements. Conley et al.'s (2004) instrument comprises four scales that focus on the core dimensions of epistemological beliefs. Our reduced version comprised 12 items in two scales, one measuring certainty (i.e., "Scientific knowledge is always true") and one measuring development of knowledge (i.e., "Some ideas in science today are different from what scientists used to think"). We used these scales only as they were the most pertinent to the focus of the study (see the Appendix). It should be pointed out that these scales substantially overlap the scales measuring simplicity and certainty in the work of Hofer (2000; Hofer & Pintrich, 1997). Items were rated on a 5-point Likert-type scale (1 = *strongly disagree*, 5 = *strongly agree*). The scale measuring certainty was reversed so that for each item of the two scales, higher scores reflected more sophisticated beliefs.

The alpha reliability coefficient of this reduced version of the instrument was .73. The total score in epistemological beliefs was dichotomized on the basis of the median and was used to create two mutually exclusive groups. One comprised students with more advanced beliefs about the nature of scientific knowledge ( $n = 40$ ; 22 in the experimental condition and 18 in the control condition), and the other comprised students with less advanced beliefs ( $n = 54$ ; 29 in the experimental condition and 25 in the control condition).

**Topic interest.** The authors devised a 10-item interest questionnaire, with items to be rated on a 5-point scale (1 = *not at all*, 5 = *much*), to measure participants' level of interest in the topic of light—the topic of the text to be read (see the Appendix). As in previous studies focused on a single topic to be learned (e.g., Boscolo & Mason, 2003; Mason & Boscolo, 2004; Schiefele, 1996; Schiefele & Krapp, 1996), a questionnaire given before text reading was considered to be a more appropriate way to measure students' evaluative orientation toward content than the simple rating of a title on a content area (e.g., Flowerday, Schraw, & Stevens, 2004). The items were formulated by taking into account the two aspects of interest that have been distinguished (Krapp, 1999; Schiefele, 1996): feeling-related and value-related valences. An example of a feeling-related item is "I would be excited about studying light in science classes." An examples of a value-related

item is "Knowing how we can see the different colors of objects is not important to me." The knowledge component, which has been included in the conceptualization of interest offered by Renninger and other scholars (Renninger, 1990, 1992, 2000; Hidi & Renninger, 2006), was not covered in this questionnaire. We did not expect to find a correlation between knowledge and interest because we assumed that young students would have very little knowledge about scientific topics and would have little understanding of the contribution of knowledge to interest. Nevertheless, the learners could have shown some interest that was based on individual and situational sources and was equated mainly with positive feelings (Renninger, 2000). Furthermore, students' low level of knowledge about the topic would allow a better examination of the role of interest.

Three items (2, 6, and 10) of the questionnaire were reversed so that for each item, higher scores reflected greater interest. The alpha reliability coefficient of this questionnaire was .80. In this case too, the total score for topic interest was dichotomized on the basis of the median and used to create two mutually exclusive groups. One was made up of students with higher topic interest ( $n = 50$ ; 29 in the experimental condition and 21 in the control condition), and the other was made up of students with lower topic interest ( $n = 44$ ; 22 in the experimental condition and 22 in the control condition).

**Prior knowledge.** Eight open-ended questions ascertained participants' preexisting conceptions about light and diffusion (Questions 2, 3, and 7), light and vision (Questions 1, 4, and 5), and light and color (Questions 6 and 8). All questions were of a generative nature (Vosniadou, 1994) and asked students to formulate an explanation for a phenomenon (see the Appendix). Some of these questions were devised by taking into account questions asked in previous studies (Guesne, 1985; Jung, 1986; La Rosa & Mayer, 1991; La Rosa, Mayer, Patrizi, & Vicentini, 1984; Ramadas & Driver, 1989; Ramadas & Shayer, 1987; Watts, 1985) and the grade level of our participants, who were younger than those involved in previous research. Each question was accompanied by a schematic representation of the phenomenon, because much of the teaching of optics in school involves ray diagrams. Diagrams of selected aspects of light-vision phenomena are also very frequent in textbooks discussing light. Some questions also asked the students to add elements to complete a schematic representation. In this case, the elements added and the explanation were considered together, one helping with the understanding of the other. The reliability of open-ended questions was .73 at pretest, .84 at the immediate posttest, and .83 at the delayed posttest.

**Reading comprehension.** Participants were individually administered an Italian standardized test for fifth grade to measure their expository text reading comprehension skills (Cornoldi & Colpo, 1995) and to tease out their correctness and rapidity in decoding. The test consists of a reading text and 10 multiple-choice questions. Students are asked to read the text silently and individually with no time constraints, but time is considered over when 9/10 of the class have finished answering the questions. Students are allowed to refer to the text whenever they need to in order to minimize the memory load. Some of the answers require information explicitly stated in the text and ask respondents to identify characters (animals, entities, etc.), actions, and events, whereas other answers require inferences.

### Reading Materials

The effects of the learning text type on conceptual change were examined by means of two versions of the same text about light. In the traditional text reading condition (control group), students were given a text that combined extracts from common science textbooks (Ajello, Girardet, & Grazzini Hoffman, 1994; Magon, 1996; Saccaro & Signorini, 1996). In the refutational text reading condition (experimental group), students were given a refutational text, which was prepared by modifying the structure of the text used in the former condition. Three parts were added but no other modifications made. Each of these three parts was written to activate, by directly stating and challenging, a specific alternative conception held by the participants. Each part added to the refutational text was written in keeping with the conceptual continuity and text flow. Text coherence was modified as little as possible with the insertion of each part. The three parts did not differ in any aspects of their structure. The first part added addressed the question of the nature and diffusion of light. It was aimed at undermining the conception of a corpuscular nature of light and the conception that the diffusion of light depends on its intensity. The second part added underlined the role of light and its relationship with vision to challenge the naïve conceptions that light alone or light and open eyes are enough to see an object. The third part added was aimed at refuting the idea that color is the property of the object, unrelated to light absorption and reflection phenomena (see the Appendix for excerpts of the traditional and refutational texts).

With these three parts included, the refutational text was much longer than the traditional one. To reduce this discrepancy, the traditional text included additional material that extended and elaborated the information provided. No marginal information was added, which would render the text less focused, therefore disadvantaging students in the control condition. The final version was 481 words, whereas the refutational text was 661 words. Given that the former was still shorter, the control group students were given a further prereading task; that is, they were asked to write down whatever came into their minds on hearing the word *light*. In this way, the amount of time dedicated to the topic was more or less the same for the two groups. Nevertheless, it should be acknowledged that this task, which could activate prior knowledge (i.e., more alternative conceptions about light), could also reduce the likelihood of conceptual change (Alvermann, Smith, & Readence, 1985). However, in this case what the participants wrote, elicited by hearing the word *light*, was not about scientific phenomena that could allow them to activate and focus on alternative representations. The students who had not dealt with light as a scientific topic reported experiences of their everyday life that came to mind. For example, a student's curtains remained open in her bedroom, so she woke up early in the morning before the alarm clock, because there was too much light in the room. Another student described a street that had been dark and was now well lit, which made people happy because they felt more comfortable walking or cycling at night.

### Postreading Materials and Tasks

*Liking the text.* In both reading conditions, students were asked to rate how much they liked the text they had read on a

5-point Likert type scale (1 = *not at all*, 5 = *very much*) and how much they liked to read science texts. These questions were aimed at ascertaining whether there would be a greater preference for the refutational text over the traditional text, which was very similar to any other traditional textbook science text.

*Retention questions.* Five open questions were asked to assess participants' ability to retain facts presented in the text by referring to famous scientists who, in the past, held different views about light. They were challenging to some extent because they were about these views, but they did not ask for any explanations and could be correctly and completely answered, with no inferences, by retaining information that was explicitly expressed in the text. In addition, the answers could be given independently of the students' own conceptions about light. Retaining what a scientist said about light did not imply any reference to their views. Thus, the responses did not represent deep thinking on the content, as did those aimed at measuring conceptual change, which required explanations on the basis of the students' own views (see the Appendix).

*Conceptual change questions.* The same generative open-ended questions used to ascertain participants' prior knowledge were asked again at both immediate and delayed posttests to examine any changes in students' conceptions as well as the stability of these changes. Answers to these questions ascertained text understanding at the level of the situation model (Kintsch, 1998), an understanding based on an integration between prior knowledge and knowledge provided by the text (see the Appendix).

### Coding

Answers to the open-ended questions, which were asked to measure text retention, were scored 0 to 2 according to their degree of correctness and completeness. No points were given for incorrect answers. One point was assigned if the answer consisted of correct but incomplete information. Two points were assigned if the question was answered correctly and completely. For instance, students were asked, "Where does light come from according to Kepler?" The answer "Light rays come from the eyes" scored 0. The answer "Light comes from a lamp" scored 1. The answer "Light rays come from all light sources, for example, the sun or a candle" scored 2. All answers were coded by two independent raters. Each rater read and scored all answers independently. Interrater agreement calculated as a percentage of agreement on the total of the answers was 94%. Disagreements were resolved in conference through discussion in the presence of a third rater.

Answers to the generative open-ended questions asked at pretest and at immediate and delayed posttests to measure conceptual change were analyzed both qualitatively and quantitatively. For the qualitative analysis, different explanation categories were identified for each of the three topics about light. For the quantitative analysis, the answer categories were scored 0 to 2 according to their degree of correctness and completeness, as were the retention questions. For example, one of the questions about vision, taken from Ramadas and Driver (1989), was the following:

A child is in a dark room and cannot see anything. When the lights are turned on in the room she sees a book on a table in front of her. How is she now able to see the book? Explain carefully what is happening

between the book and her eyes. You can draw lines on the diagram to help your explanation. (p. 103)

No points were assigned to unclear or irrelevant answers or to answers expressing alternative conceptions like the following: "The light brightens the book on the table"; "The light brightens up the book. At this point the child can see it. The light illuminates the table well but not all the room"; "When the light is turned on, light rays reach the child's eyes and the book on the table, so she can see it." One point was given for correct but incomplete answers; for example, "The light ray hits the object, so that the child's eye can see it." Two points were given to correct and more complete/elaborated answers; for example, "The rays of the lamp bounce off the book and go to the eyes of the child, who is able to see the book."

All answers were coded by the same two independent raters. Interrater agreement calculated as a percentage of agreement on the total of the answers was 93%. Disagreements were resolved in conference through discussion in the presence of a third rater. Questions are reported in the Appendix.

### Procedure

Data gathering took place in three sessions. The topic of light had not been dealt with previously in any of the students' classes. It is a topic studied in fifth grade, so the teachers' cooperation was extremely valuable. In the first session (pretest), the order of tasks was (a) epistemological beliefs questionnaire, (b) pretest generative open-ended questions, and (c) reading comprehension test. The session took about 2 hr. The second session took place about 1 week after the first. In one condition, participants were asked to study the traditional text, whereas participants in the other condition were asked to study the refutational text. After studying the text (immediate posttest), participants were asked to rate their liking of the text they read and the texts they usually read in their schoolbook, and they were asked to answer the text retention questions and the open-ended generative questions. This session also took about 2 hr. The third session (delayed posttest) took place 2 months after the posttest and lasted about 1.25 hr. Participants were again asked the text retention questions and the open-ended generative questions. Between the immediate and the delayed posttests, the topic of light was not discussed at all in the classrooms to avoid interference from other instructional variables.

### Results

Four *t* tests, controlled for error rates, were performed first to ensure the equivalence of the groups in the two reading conditions, refutational and traditional text, for all the examined measures. The results show that before the reading tasks, there were no statistically significant differences between the two groups of students for any of the measures: epistemological beliefs (refutational:  $M = 37.76$ ,  $SD = 5.78$ ; traditional:  $M = 37.93$ ,  $SD = 5.19$ ),  $t(92) = 0.14$ ,  $p = .88$ ; topic interest (refutational:  $M = 35.55$ ,  $SD = 7.79$ ; traditional:  $M = 36.30$ ,  $SD = 5.99$ ),  $t(92) = 0.51$ ,  $p = .60$ ; prior knowledge (refutational:  $M = 0.29$ ,  $SD = 0.61$ ; traditional:  $M = 0.37$ ,  $SD = 0.92$ ),  $t(92) = 0.48$ ,  $p = .62$ ; and reading comprehensions skills (refutational:  $M = 10.13$ ,  $SD = 2.10$ ; traditional:  $M = 10.51$ ,  $SD = 2.13$ ),  $t(92) = 1.42$ ,  $p = .15$ . As

expected, prior topic knowledge and interest were not correlated ( $r = .01$ ,  $p = .91$ ).

In all the subsequent statistical analyses, the variables of epistemological beliefs and topic interest were dichotomized for two reasons. First, given the nonlinear relation between the dependent and independent variables, the dichotomization would increase the power of the statistical design. Second, the use of the full range value of the variables would have implied a repeated multivariate analysis with one independent variable (type of text) and three covariates (epistemological beliefs, topic interest, and reading comprehension skills), with unclear outcomes. Because we were interested in maximizing the possibility of attaining results that were as clear and interpretable as possible, we opted for the dichotomized variables. This allowed an analysis that offered a clear interpretation of the differences between the two groups.

### Text Retention

A repeated measures analysis of covariance (ANCOVA), with text type (traditional and refutational), epistemological beliefs (less advanced and more advanced), and topic interest (lower and higher) as between-subject variables, with time (immediate posttest and delayed posttest) as the within-subject variable, and with reading comprehension as the covariate, was carried out. It revealed only the effect of the covariate,  $F(1, 85) = 6.25$ ,  $p < .05$ ,  $\eta^2 = .07$ . This means that at both immediate and delayed posttests, reading comprehension skills correlated significantly with the retention of facts introduced in the text. None of the other variables examined affected this more shallow level of text understanding at the two testing times.

### Overall Conceptual Change

Overall changes in explanations about light, vision, and color were measured through a repeated measures ANCOVA with text type (traditional and refutational), epistemological beliefs (less advanced and more advanced), and topic interest (low and high) as between-subject variables, with conceptual knowledge at the three different testing times (pretest, immediate posttest, and delayed posttest) as the within-subject variables, and with reading comprehension as the covariate. From this analysis, the Time  $\times$  Text Type interaction,  $F(2, 84) = 8.31$ ,  $p = .001$ ,  $\eta^2 = .16$ , the Time  $\times$  Topic Interest interaction,  $F(2, 84) = 7.18$ ,  $p = .001$ ,  $\eta^2 = .14$ , and the Time  $\times$  Text Type  $\times$  Topic Interest  $\times$  Epistemological Beliefs interaction,  $F(2, 84) = 4.43$ ,  $p < .05$ ,  $\eta^2 = .09$ , emerged. The analysis also revealed that the covariate, reading comprehension ability, correlated significantly with the three scores,  $F(2, 84) = 9.98$ ,  $p < .001$ ,  $\eta^2 = .19$ .

Regarding the Testing Time  $\times$  Text Type interaction, students who received information from the refutational text were facilitated in conceptual change much more than those who read the traditional text. The former scored higher than the latter at delayed posttest, but their scores decreased more from the immediate posttest to the delayed posttest.

Regarding the Testing Time  $\times$  Topic Interest interaction, participants with high interest outscored students with low motivational involvement at both testing times. Moreover, from the immediate to the delayed posttest, the scores of the highly inter-

ested students decreased more than those of the less interested students, whose scores remained the same.

From the interaction among all three variables, it emerged that at both testing times, the highest scores for conceptual change were obtained by learners with high topic interest, those with more advanced epistemological beliefs, and those who read the refutational text, although these scores decreased significantly from the immediate to the delayed posttest. Scores for students in the experimental condition with low topic interest but more advanced epistemological beliefs increased slightly at the delayed posttest. The same result emerged for the control condition students with low topic interest and less advanced beliefs about the nature of scientific knowledge. The interaction among all three variables can be seen in Figure 1.

Because the refutational text addressed conceptions about three partly connected phenomena, that is, the propagation of light, the relationship between light and vision, and the origin of color, a finer-grained analysis was also carried out to examine in depth the effect of the independent variables on changes in conceptions about each phenomenon. The next sections present the results of this analysis.

### *Conceptual Change About the Nature and Propagation of Light*

A repeated measures ANCOVA with the same between-subject variables and the same covariate, but with the scores of conceptual knowledge about the nature and propagation of light as within-subject variables, revealed a significant Time  $\times$  Text Type interaction,  $F(2, 84) = 10.07, p < .001, \eta^2 = .19$ . Students who read the refutational text changed their conceptions about these aspects of light much more than students who read the traditional text. The scores for their explanations were higher at both testing times (Table 1). Learner variables did not affect conceptual change, except for the covariate of reading comprehension skills,  $F(2, 84) = 7.72, p < .01, \eta^2 = .13$ .

A qualitative analysis identified the conception categories held by students prior to and after text reading (see Table 2). The refutational text was mainly successful in prompting a change in the most common misconception, that is, light as rays that propagate around the light source. It also promoted a change in the alternative conception of light as particles that propagate around the light source. However, not all learners were able to construct scientific knowledge. To illustrate conceptual change due to text reading, which is representative of the data analyzed, we report an example explanation given by a participant (P96, refutational text reading, high topic interest, and more advanced epistemological beliefs) to the third question (see the Appendix). It shows revision of personal conceptions from pretest to posttest.

Pretest: "I have drawn the light which is still and illuminates a specific point."

Immediate posttest: "I have drawn the light rays that do not meet any obstacle so they diffuse in all directions."

### *Conceptual Change About Vision*

A similar repeated measures ANCOVA, with the scores for conceptual knowledge about the relationship of light and vision as within-subject variables, revealed a significant Time  $\times$  Text Type interaction,  $F(2, 84) = 7.77, p = .001, \eta^2 = .15$ , a Time  $\times$  Topic Interest interaction,  $F(2, 84) = 4.06, p < .05, \eta^2 = .09$ , and a Time  $\times$  Text Type  $\times$  Topic Interest  $\times$  Epistemological Beliefs interaction,  $F(2, 84) = 3.41, p < .05, \eta^2 = .07$ . Alternative conceptions about the role of light and its relationship with vision changed more for students who read the refutational text and had high topic interest. At both testing times, the interaction among all three variables showed that more conceptual change was produced by students who read the refutational text and had high topic interest. This interaction also showed that these students had more advanced beliefs about the certainty and development of scientific knowledge (see Table 3). In addition, the ANCOVA revealed a

Figure 1. Overall scores for conceptual change showing the interaction between text type, topic interest (int), and epistemological beliefs (bel). adv = advanced.

Note. Adjustment by covariate of reading comprehension.

significant effect of the covariate, reading comprehension skills,  $F(2, 84) = 9.54, p < .001, \eta^2 = .18$ .

A qualitative analysis identified the conception categories held by students prior to and after text reading (see Table 4). In this case, the refutational text was especially successful in prompting a change in the common, targeted misconception that as well as light, our eyes have an active role in seeing an object. Not all readers, however, were able to learn the new scientific knowledge from the text. The following is a representative example of conceptual change about light and vision as reflected in the explanations given by a participant (P33, refutational text reading, low topic interest, and less advanced epistemological beliefs) to the first question (see the Appendix).

Pretest: "Light illuminates the book on the table and she sees it."

Delayed posttest: "In my opinion the light diffuses in the whole room; a light ray hits the book, it makes the ray bounce off the book, so that it comes to our eyes and we are able to see the colored object."

Conceptual Change About Color

Our last repeated measures ANCOVA, with the scores for conceptual knowledge about color as within-subject variables, revealed only the significant Time  $\times$  Topic Interest interaction,  $F(2, 84) = 3.32, p = .05, \eta^2 = .07$ . Students who reported that they were interested in knowing about light and attributed more importance to the topic were those who changed their naïve conceptions about color more (see Table 5). Only in this analysis did the effect of the covariate, reading comprehension skills, not emerge.

Note. Adjustment by covariate of reading comprehension.

A qualitative analysis identified the conception categories held by students prior to and after text reading (see Table 6). In this case, the refutational text was not powerful in prompting the restructuring of the targeted alternative conception that color is a property of an object. Changes in explanations about color were infrequent and can be illustrated, as an example, by the following participant's answer (P43, refutational text reading, high topic interest, and more advanced epistemological beliefs) to the sixth question (see the Appendix).

Pretest: "I have drawn an arrow to show that the child is looking at the orange. She sees it as orange because its skin is orange."

Delayed posttest: "Light, which is made up of the different colors of the rainbow, absorbs all colors but the orange, so the child sees the orange as orange."

### Liking the Reading Text

For the control group students, a *t* test to compare ratings of how much they liked the text they read revealed no significant difference between the two ratings,  $t(92) = 1.30$ ,  $p = .195$ . Students perceived the text they had just read in the same way as any other science text they were familiar with. On the contrary, for the experimental group, who read the refutational text, a *t* test revealed a significant difference,  $t(92) = 4.16$ ,  $p < .001$ . The unusual text ( $M = 4.24$ ,  $SD = 1.05$ ) just read, which stated and challenged their conceptions, was liked more than the normal textbook science texts ( $M = 3.51$ ,  $SD = 1.17$ ).

### Discussion

This study was aimed at examining the interplay between instructional text and learner variables that may affect conceptual change. Three variables were examined, which had been investigated separately or in pairs in previous research: the structure of the text to be read to gain new knowledge, epistemological beliefs, and topic interest. Two types of instructional texts were used: an ordinary expository science text whose primary function was to give new information and a refutational text that not only gave new, correct information but also explicitly stated and refuted alternative conceptions by presenting the scientific conceptions as viable alternatives. It should be underlined that, as in most previous research on knowledge restructuring, in this study epistemological beliefs reflect more or less advanced representations about only two aspects of scientific knowledge, that is, its nature and its development (simple and certain vs. complex and continuously evolving), and not epistemological beliefs at large. However, these two belief dimensions are the most pertinent to the focus of the study. Topic interest reflects lower or higher affective orientation toward the topic examined.

Our first research question examined whether participants' text retention would be affected by text type, epistemological beliefs, topic interest, and/or their interaction. The findings confirm our hypothesis because none of the examined variables affected the shallow level of text understanding related to retention of factual information. Only the covariate, reading comprehension ability, correlated with the dependent variable.

The second research question examined whether students' overall conceptual change as well as the various aspects of light addressed—which were reflected in their answers to open-ended questions—would be affected by text type, epistemological beliefs, and topic interest. Findings partially confirm our hypotheses. Overall, the positive effect of reading the refutational text confirms previous research (Guzzetti et al., 1993, 1997) and, in particular, confirms an investigation that involved fifth graders learning about energy (Diakidoy et al., 2003), although it did not explicitly address pre- and postreading conceptions about the topic.

Topic interest was also a resource in the knowledge revision process. It must be pointed out that the motivational variable did not correlate with prior knowledge, as emerged from previous studies carried out with much older students (Andre & Windschitl, 2003; Venville & Treagust, 1998). Thus, a higher degree of interest did not mean a higher number of initial alternative conceptions. This could have been because our participants' initial knowledge was generally very limited, so high interest in the topic could be

expressed by students who knew very little about light and not only by those who had high (alternative) prior knowledge. When interest is equated with positive feelings in particular, it may be associated with a low level of content knowledge or little awareness about the contribution of knowledge to interest (e.g., Renninger, 2000).

The main effect of epistemological beliefs did not emerge. However, a significant interaction among convictions about the nature and stability of scientific knowledge, topic interest, and text type, in relation with testing time, has been found generally. As hypothesized, an effective combination of all three factors emerged, although the effect was modest. More conceptual change was produced by students who read the refutational text, those who had more advanced epistemological beliefs, and those with high topic interest. Although when compared with the others these students' performances decreased from the immediate to the delayed posttest, they were still the highest 2 months after reading the

instructional text. This outcome could have been due to the powerful combination of topic interest, which promotes attention arousal, and the other two resources, epistemological beliefs and refutational text. The latter have the potential to help students recognize, more or less directly, the limitations of their own conceptions, to be dissatisfied with them, and to try to make sense of the new knowledge. The advantageous interaction among the three factors may be related to the notion of intentionality in conceptual change (Sinatra & Pintrich, 2003a). These factors could help make learning through conceptual revision a goal to be deliberately pursued (Hynd, 2003; Mason, 2003) to improve current understanding of the phenomena examined.

The interaction among epistemological beliefs, topic interest, and text type sustains deep processing (Alexander et al., 1994). However, processing during text reading (Kardash & Howell, 2000) was not the focus of the current study, and we do not have direct information about whether readers with different epistemo-

logical beliefs and topic interest process text differently in the two reading conditions. As an alternative explanation, it could be speculated that these students might have—without deep processing—simply noted discrepancies in conceptions. However, this alternative seems less likely in light of the literature on conceptual change, which underlines that it is a demanding process in many respects. In any case, further research is needed to examine the mechanisms through which the beneficial effects of these factors are activated.

In addition, an overall compensation effect of the instructional and motivational variables emerged. Reading an innovative text, which activates and challenges readers' prior knowledge, unlike traditional science texts, compensated for low levels of interest in the topic and less sophisticated convictions about scientific knowledge. Overall, these data confirm a previous study on the relationship between epistemological beliefs and reading a refutational text, from which a powerful combination of the personal and instructional variables also emerged (Mason & Gava, 2007).

The overall outcomes were also found in the finer grained analysis of the change in conceptions about the second phenomenon considered: light in relation to vision. Refutational text and topic interest as separate variables, as well as the interaction between all three variables tested, affected how misconceptions were overcome in favor of the scientific explanation, although not all students abandoned their alternative ideas.

The analysis of conceptual change about the first phenomenon of light addressed, its nature and diffusion, revealed that it was affected only by the type of text read. Specifically, the refutational text succeeded in prompting change in the most commonly held misconceptions, that is, light as rays or particles that propagate only around the source.

A finer grained analysis of conceptual change about the third phenomenon addressed, color, revealed that the refutational text was relatively ineffective in advancing students' scientific knowl-

edge. Only high topic interest helped participants learn more about the scientific conception of the origin of an object's color. The alternative idea of color as a property was the most difficult to change. An explanation for this outcome cannot refer to differences in the refutation provided in that part of the refutational text, because it did not differ in any respect from the previous two parts that were more effective. It can be argued that the scientific conception of the origin of color seems not only as abstract and complex as the others, especially for young students, but also counterintuitive. It is particularly hard to understand that size and shape are properties of an apple but color is not and that its redness must be conceived in relation to the light that the apple reflects. It should be pointed out that in the history of science, the idea that light is not white or yellow but rather contains all colors and the idea that materials absorb some of these colors while reflecting others appeared later than the currently accepted ideas about the nature and propagation of light as well as about vision phenomena.

Furthermore, the correlation between reading comprehension ability and change of conceptions highlights, once again, the importance of this ability in academic learning. Improving students' reading comprehension is, in any case, an essential way to support their conceptual learning from a text.

The overall decreased performance from the immediate to the delayed posttest could be expected, to some extent. The higher decrease in the scores of students with high interest who were in the refutational text condition (see Figure 1) may be explained by a prereading topic interest that was mainly an expression of situational interest elicited by the words and sentences that presented the topic. Topic interest measured in the study could therefore be mainly the expression of a triggered situational interest, that is, a characteristic of the first phase of interest development (Hidi & Renninger, 2006).

The overall increased performance from the immediate to the delayed posttest by students in the experimental condition (those

with more advanced epistemological beliefs and low topic interest) and students in the control condition (those with less advanced epistemological beliefs and low topic interest) cannot be explained by further teaching about light, because the teachers did not deal with this topic during the 2-month period that elapsed between the immediate and delayed posttest. It could be speculated that studying other physics topics may have indirectly helped the students to understand the light phenomena better. However, this hypothesis is rather weak because teachers covered the human cardiovascular and respiratory systems in the interim 2-month period. As an alternative, it could be speculated that students might have had further opportunities to learn about light during the interval by discussing the answers with each other or with their parents and other knowledgeable adults. To some extent, they could have therefore processed the target concepts in the period between the two posttests, perhaps also supported by an increased interest in the topic triggered by the text and questions (Hidi & Renninger, 2006; Renninger et al., 2002).

The third research question asked if students liked the refutational text more than the traditional one. As hypothesized, the refutational text, which helped more in the revision of preexisting conceptions, was perceived as more likeable than the typical textbook text. This outcome is in line with previous research (Guzzetti et al., 1995). Reading a text that made their representations explicit but also highlighted their limitations in favor of scientific ones was a more likeable activity than reading a typical scientific text that transmits knowledge. In this regard, perception of the ease of a learning text could be a key factor in text liking.

Finally, it should also be pointed out that this study examined conceptual change in a complex topic as a consequence of reading one text, and this is a limitation. However, this is what happens in regular classrooms, at least in Italy, from the last years of primary school onward. New knowledge has to be acquired mainly from text and picture reading, especially when abstract concepts are dealt with and the possibilities of experimentation in the classroom are very limited. We agree that conceptual understanding in physics is the product of a gradual and complex process that requires time (Stathopoulou & Vosniadou, 2007). A deeper and more complete understanding of the topic, even at the fifth-grade level, certainly requires more learning activities than the study of one text. Nevertheless, reading a refutational text can be considered a productive starting point for a long and demanding process.

### Conclusion

To conclude, this study documents the role of two learner factors considered in theory by Pintrich and colleagues (Pintrich, 1999; Pintrich et al., 1993) as possible motivational resources for the multifaceted process of conceptual change. These factors, epistemological beliefs and interest, may interact with the instructional material. Higher topic interest was found to be effective in itself and in the interaction with epistemological beliefs and the text type to be learned. A refutational text was also found to facilitate students' understanding of new concepts even when the characteristics of the participants examined were not supportive. This outcome leads us to highlight the potential of refutational texts, especially for the acquisition of concepts that cannot be presented in the classroom through observation and experimentation. The use of refutational texts could also increase students'

situational interest (Hidi, 1990; Krapp, Hidi, & Renninger, 1992; Schraw & Lehman, 2001), which is triggered by specific features of a stimulus or situation, such as text characteristics. In this regard, research has documented that potential situational interest sources are ease of comprehension, text cohesion, concreteness, vividness, engagement, and emotiveness. The most effective sources of situational interest in text learning were found to be ease of comprehension, vividness, and concreteness (Sadoski, 2001; Schraw et al., 1995; Schraw, Flowerday, & Lehman, 2001). It is more likely that a refutational, rather than a traditional, text would be perceived as having these characteristics.

More sophisticated beliefs about the certainty and development of scientific knowledge were found to be effective when these beliefs interacted with all other variables examined. That is, they were best as resources in conjunction with attention arousal, which was stimulated by topic interest, and in relation to reading a text that helped students recognize the limitations of their conceptions and the value of scientific ones. Activities and contexts devised to sustain the development of beliefs about the nature of knowledge are more or less indirect ways to favor the knowledge revision process (Mason, 2002).

In summary, the interplay of factors in text learning that emerged from this study indicate that we have moved beyond cold conceptual change, at least to some extent, and are following the warming trend (Sinatra, 2005). The implications of our findings for conceptual change research highlight that new models of knowledge restructuring must take into consideration the complexity of the process, that is, its multifaceted interactive nature (Sinatra & Mason, *in press*). Models that focus only or mainly on one of the various factors involved in the process cannot account for this complexity or serve as powerful tools for implementing feasible educational interventions aimed at effectively promoting disciplinary knowledge construction and reconstruction in the classroom. It has been recognized that the progress of the research in this multidimensional arena regarding conceptual change may not always be certain and stable (Alexander & Sinatra, 2007). Nevertheless, it is compelling to follow the warming trend (Sinatra, 2005) to increase psychologists' understanding of the complex interplay among key factors underlying conceptual change in the classroom.

From the standpoint of science learning, our findings highlight that if learners hold alternative conceptions, these must be identified in order to tailor instruction to their need for more or less radical knowledge restructuring. The disciplinary material to be learned, for example, the texts to be studied, must be carefully prepared to trigger situational interest. If sustained, this may evolve into a maintained situational interest and gradually into an individual interest (Hidi & Renninger, 2006). This means increasing the likelihood that the new science content is integrated, and not just juxtaposed, into the students' network of conceptions. However, increasing the level of students' understanding of scientific phenomena does not mean that science teaching processes must focus only on conceptual structures, those of the learners, which very often need to be restructured, and those of the disciplinary domain, which are to be acquired. Other noncognitive factors that play an important role in learning processes (motivation in particular) should be taken into consideration. Learners' epistemological representations of the nature of the scientific knowledge they are dealing with, as well as their interest in the content of the knowledge they are asked to understand, are only two of the other factors that affect conceptual change in the classroom.

## Questionnaires, Open-Ended Questions, and Excerpts From the Texts Used in the Study

### The Two Scales Used to Measure Epistemological Beliefs About the Certainty and Development of Science

These two scales are taken from Conley et al.'s (2004, pp. 203–204) questionnaire.

#### *Certainty*

All questions in science have only one right answer.

The most important part of doing science is arriving at the right answer.

Scientists know pretty well everything about science; there is not much more to know.

Scientific knowledge is always true.

Once scientists have the result of an experiment, that becomes the only answer.

Scientists always agree about what is true in science.

#### *Development*

Some ideas in science today are different than what scientists used to think.

The ideas in science books sometimes change.

There are some questions that even scientists cannot answer.

Ideas in science sometimes change.

New discoveries can change what scientists think is true.

Sometimes scientists change their minds about what is true in science.

### The Questionnaire Used to Measure Topic Interest

1. I would be excited about studying light in science classes.
2. I think that there are many more relevant topics than light to learn about in science classes.
3. I think it is important to know what the light we see is made of.
4. If I came across a TV program that talked about light and colors, I would be keen to understand it.
5. I think that during science classes some time could be devoted to talking about light and colors.

6. I am not interested in knowing more scientific aspects of light.
7. I think that light is a difficult but worthwhile topic of science.
8. I would get involved in knowing how we can see the objects around us.
9. I am keen to know what light really is and its characteristics.
10. Knowing how we can see the different colors of objects is not important to me.

### Open-Ended Questions to Measure Text Retention

1. Where does light come from according to Euclid?
2. How does light propagate according to Euclid?
3. Where does light come from according to Kepler?
4. What happens when a light ray hits an object according to Kepler?
5. What did Newton discover about light?

### Open-Ended Questions to Measure Conceptual Change (Deep Text Understanding)

Each question included a diagram, omitted here because of space restrictions.

1. A child is in a dark room and cannot see anything. When the lights are turned on in the room she sees a book on a table in front of her. How is she now able to see the book? Explain carefully what is happening between the book and her eyes. You can draw lines on the diagram to help your explanation (from Ramadas & Driver, 1989, p. 103).
2. It is a dark moonless night. You see a small lamp shining far away. Show where there is light in this drawing. Then, explain why you think that the light is where you drew it (from Ramadas & Driver, 1989, p. 36).
3. In this diagram there is a candle. Draw the light of the candle to show what happens when the candle burns. Explain what you have drawn.
4. Imagine that a person enters a room where there is the candle burning. The person stays in a corner. In your opinion, can the person see the candle? Draw, and then explain what happens.
5. The child in this diagram uses the slide projector to look

at slides of when he was younger. Draw what happens when the projector is turned on. Then, explain how the child is able to see the slides (from Watts, 1985, p. 185).

6. Mark is looking at an orange on the table. Explain why he sees the orange as an orange color.
7. On a clear night a car is parked on a straight street with the lights turned on. A pedestrian who stops on the street can see the car's lights. In the diagram the street is divided into four sections. In which parts is there light? Explain your answer (from La Rosa & Mayer, 1991, p. 197).
8. Marta is looking at the new yellow t-shirt that she got as a present. Explain why she sees it as a yellow color.

#### Excerpt From the Traditional Expository Text

Thanks to Kepler's studies, we now know that light diffuses in a straight line in all directions. Light moves from its source along infinite straight paths called "rays". It continues to diffuse until it meets an object. All bodies that emit light (e.g., the sun and stars)

are called primary light sources. In contrast, the bodies that receive light are called secondary light sources. When the light rays hit an object, they bounce off it and reach our eyes.

#### Excerpt From the Refutational Text

Thanks to Kepler's studies we now know that light diffuses in a straight line in all directions. Some children, however, believe that light diffuses into the environment around the light source only up to a certain point. They believe this because they think that light gets used up as it moves further from the source. If you also think in this way, your conception is not correct. Light moves away from its source along infinite straight paths that are called "rays". It continues to diffuse until it meets an object. The area around the light source appears brighter to us only because there the light rays are closer together, while they broaden as they diffuse in all the surrounding area. When the light rays hit an object, they bounce off it and reach our eyes.

# Relationships of Three Components of Reading Fluency to Reading Comprehension

Susan Lutz Klauda and John T. Guthrie  
University of Maryland, College Park

This study examined the relationships of 3 levels of reading fluency—the individual word, the syntactic unit, and the whole passage—to reading comprehension among 278 5th graders heterogeneous in reading ability. Hierarchical regression analyses revealed that reading fluency at each level related uniquely to performance on a standardized reading comprehension test in a model including inferencing skill and background knowledge. The study supports an automaticity effect for word recognition speed and an automaticity-like effect related to syntactic processing skill. In addition, hierarchical regressions using longitudinal data suggest that fluency and reading comprehension have a bidirectional relationship. The discussion emphasizes the theoretical expansion of reading fluency to 3 levels of cognitive processes and the relations of these processes to reading comprehension.

**Keywords:** reading comprehension, reading fluency, prosody, word recognition speed, syntactic processing

Recently, there has been increased attention to reading fluency. The individual constituents of fluency (Schwanenflugel, Hamilton, Kuhn, Wisenbaker, & Stahl, 2004; Wolf & Katzir-Cohen, 2001) and the relationship of fluency to comprehension (Jenkins, Fuchs, van den Broek, Espin, & Deno, 2003b; Kuhn & Stahl, 2003) have been of particular interest.

Although speed and accuracy in reading have long been considered hallmark components of fluency (Fuchs, Fuchs, Hosp, & Jenkins, 2001), appropriate expression is now considered an additional defining component (Kuhn & Stahl, 2003; National Reading Panel, 2000). Appropriate expression refers to using prosodic features of language, such as emphasis, pitch changes, pause placement and duration, and phrasing in accord with syntactic structure so that text is translated aloud with the tonal and rhythmic characteristics of everyday speech (Dowhower, 1991; Kuhn & Stahl, 2003). In the present study, we abide by this definition, while recognizing that the terms *expressiveness* and *prosody* are occasionally used differentially (e.g., Cowie, Douglas-Cowie, & Wichmann, 2002).

It is also useful to consider fluency in terms of the text units, or levels, at which one is fluent. However, as stated by Wolf and Katzir-Cohen (2001), “Few current approaches attempt to define fluency in terms of either its component parts or its various levels of reading subskills—that is, letter, letter pattern, word, sentence, and passage” (p. 218). In the present study, we investigated fluency at the latter three of these levels, with emphasis on speed and accuracy at the word level and aspects of prosody at the sentence and passage levels.

## Relationship Between Fluency and Comprehension

Empirical studies of the relationships among reading skills have often reported moderate to high positive correlations between measures of fluency and comprehension. These correlations appear in research involving students from elementary through high school. Moreover, the studies represent large, diverse samples of students and smaller, focused samples, such as middle-school children with reading disabilities, and have used a variety of measures of fluency and comprehension (e.g., Daane, Campbell, Grigg, Goodman, & Oranje, 2005; Fuchs, Fuchs, & Maxwell, 1988; Jenkins et al., 2003b; Pinnell, Pikulski, Wixson, Campbell, Gough, & Beatty, 1995; Rasinski et al., 2005; Yovanoff, Duesbery, Alonzo, & Tindal, 2005). In addition, interventions that focus on increasing fluency have often been associated with significant gains in both fluency and comprehension, as well as correlations between the gains in each skill, for new readers and for struggling readers through high school (see reviews by Chard, Vaughn, & Tyler, 2002; Kuhn & Stahl, 2003; National Reading Panel, 2000).

Some studies, however, have indicated dissociations between fluency and comprehension when fluency is defined as accuracy or speed in reading individual words or pseudowords. For example, Oakhill, Cain, and Bryant (2003) found that different sets of component skills predicted word recognition and comprehension in average 7- to 9-year-old readers. However, a measure of syntactic processing predicted variance in both word recognition and

comprehension. In addition, Jackson and Doellinger (2002) identified six university students from a group of 17 poor recoders who comprehended as well as their peers with average recoding and comprehension skills, thereby suggesting that some poor recoders develop compensatory mechanisms that aid their comprehension. Similarly, Walczyk, Marsiglia, Johns, and Bryan (2004) found that when third graders read aloud under unrestricted circumstances (i.e., without time pressure, after listening to a model who used compensation techniques, and with the knowledge that their comprehension of what they read would be tested), literal comprehension did not correlate with accuracy in reading a list of words unrelated to the comprehension texts.

### Explaining Links Between Fluency and Comprehension

There are two major theoretical views of the processes by which fluency and comprehension may be related, one focusing on fluency at the word level and the other on fluency at the syntactic level, or fluency in reading sentences and phrases. Moreover, consideration of fluency at a third level—that of the passage as a whole—may add to our understanding of the links between fluency and comprehension. Specifically, we investigated whether fluency at the passage level, based on processing of passage-level features, or understanding of the macrostructure of the text (Kintsch & Kintsch, 2005) would add to the prediction of comprehension beyond fluency at the word and syntactic levels.

#### *Word Level*

According to automaticity theory (LaBerge & Samuels, 1974) and verbal efficiency theory (Perfetti, 1985), growth in fluency, specifically in the speed component, facilitates reading comprehension. That is, as word recognition becomes faster, it eventually becomes automatic, allowing the attention that was once required for the task of word decoding to be devoted to comprehension. Correlations between word reading speed, for words presented in list as well as passage form, and comprehension provide support for this view (e.g., Fuchs, Fuchs, & Maxwell; Jenkins et al., 2003b; McCormick & Samuels, 1979; Perfetti & Hogaboam, 1975). Furthermore, Schwanenflugel et al. (2004) found that reading with prosody did not contribute above and beyond efficiency of word recognition to the prediction of comprehension, suggesting that automaticity theory alone might be sufficient to explain the relationship between fluency and comprehension. An alternative to automaticity theory to account for relationships between word reading speed and comprehension is interactive theory. According to Rumelhart (1994) and others, top-down processes of language comprehension (e.g., syntactic knowledge) facilitate word recognition speed. We do not attempt to distinguish between these theories in this study.

#### *Syntactic Level*

Theoretically, comprehension and fluency may also be related because they share a basis in some of the semantic and syntactic processes involved in processing language at the phrase or sentence level (Jenkins et al., 2003b). Although Jenkins et al. (2003b) focused primarily on the semantic processes, we focus more on the

role of syntactic processing of sentences as an individual constituent of fluency and contributor to comprehension.

Support for the view that syntactic processing is an important element of fluency comes from work by Rasinski (1985), revealing that the ability to parse text into meaningful phrases mediated the relationship between word recognition and fluency development in good and average third- through fifth-grade readers. In addition, Berninger, Abbott, Billingsley, and Nagy (2001) identified a subtype of disabled readers characterized by errors in executive coordination at the sentence level, including inattention to syntax (represented by misordering words) and failure to read with prosody. Furthermore, as posited by Schreiber (1980) and substantiated by Dowhower (1987), the intervention method of repeated readings (Samuels, 1979) appears to lead to gains in fluency and comprehension, not because of the practice it affords for word recognition but at least partly because it forces readers to learn to compensate for the lack of prosodic cues in written text by instead using syntactic as well as semantic, morphological, and contextual cues.

Further evidence, according to both Young and Bowers (1995) and Kuhn and Stahl (2003), that syntactic processing contributes to comprehension comes from two categories of studies: (a) those showing that training readers to segment text into meaningful phrases or giving them text that has already been segmented results in better comprehension (e.g., Amble & Kelly, 1970; Cromer, 1970; Mason & Kendall, 1979; O'Shea & Sindelar, 1983) and (b) those showing that teaching children to identify words faster, although associated with gains in decoding speed, is not linked with significant gains in comprehension of text composed of the trained words (e.g., Fleisher, Jenkins, & Pany, 1979; Grant & Standing, 1989; Spring, Blunden, & Gatheral, 1981).

#### *Passage Level*

In addition to sharing a basis in processes at the phrase and sentence level, fluency and comprehension may depend on processes relevant to the passage as a connected whole. That is, to some degree, performance on fluency and comprehension tasks that involve reading passages (either silently or out loud) may both be reliant on processing of features that lend the text an overall organization and coherence or, as termed by Kintsch and Kintsch (2005), the macrostructure of the text.

For narrative passages, these features may include categories of story grammar, such as those formulated by Stein and Glenn (Stein, 1979; Stein & Glenn, 1979) for a simple story: setting, initiating event, internal response, attempt, consequence, and a reaction. Empirical research has provided clear evidence that understanding story grammar aids reading comprehension (see Olson & Gee's review, 1988), and we posit that an understanding of story grammar might also assist reading fluency, namely the prosodic or expressive aspects of it. In other words, when a reader encounters a section of a passage that fits into one of the story grammar categories, the reader will mark that section with appropriate prosodic features if the reader has developed awareness of that category of story grammar.

For expository passages, developing an understanding of the macrostructure involves discerning the overall purpose or basic organizational structure of the text, which, according to Meyer, Young, and Bartlett (1989), may be causation, description, se-

quence, problem solution, or comparison. Each structure is associated with signaling words. For example, *as a result*, *because*, and *in order to* indicate the causation structure. Meyer and colleagues (e.g., Meyer, 1999; Meyer et al., 2002, 1989) have found clear links between identification of expository text structures and comprehension for both children and adults, but as with narrative passages, apparently no studies have investigated whether awareness of the text structure is also associated with fluency.

The highest levels of rubrics that have been used to assess the quality of children's passage oral reading place some emphasis on the expressiveness dimension of fluency, implying that the best readers have a sense of the passage's macrostructure. For example, to be rated at the highest level of the 1 to 4 scoring rubric used in the studies of oral reading fluency conducted by the National Assessment of Educational Progress (Daane et al., 2005; Pinnell et al., 1995), the reading must meet the criteria that "some or most of the story is read with expressive interpretation" (Daane et al., 2005, p. 28). To distinguish the potential differential relations of syntactic understanding at the sentence level and expressiveness at the passage level with comprehension, these variables were rated independently in the current study.

### Mediators of the Relationship Between Fluency and Comprehension

Automaticity theory (LaBerge & Samuels, 1974) posits that automatic word recognition frees resources for higher level processes involved in comprehension. However, few researchers have endeavored to determine exactly which processes are given attention once automaticity in word recognition is achieved. In line with Kintsch (1988, 1998); Graesser, Singer, and Trabasso (1994); and Thurlow and van den Broek (1997), we view inferencing and the integration of one's knowledge base with the text that one is reading as key higher order processes involved in comprehension. Thus, we also investigated whether these were indeed processes that became more active with growth in fluency or, in other words, whether they mediated the relationship between fluency and comprehension.

### Directionality of the Relationship Between Fluency and Comprehension

The direction of causality between fluency and comprehension is currently a matter of some debate (Wolf & Katzir-Cohen, 2001). As pointed out by Stecker, Roser, and Martinez (1998), there is evidence that fluency is both a contributor to and a product of comprehension; they thus advocated viewing comprehension and fluency as having a reciprocal causal relationship, a view currently espoused by practitioners as well as reading researchers (Pikulski & Chard, 2005). Traditionally, however, researchers have theorized that fluency primarily facilitates comprehension, in line with automaticity theory (LaBerge & Samuels, 1974). In contrast, others such as Kuhn and Stahl (2003) and Young and Bowers (1995) have contended that appropriate application of prosodic features, along with speed in word recognition, plays an important role in facilitating comprehension.

Others view the relationship between fluency and comprehension as varying to some degree in relation to one's reading skill. Jenkins et al.'s (2003a) findings indicated, for example, that com-

prehension may especially facilitate fluency for children of higher reading ability, whereas weak word recognition skills may be what limit the fluency and comprehension development of poor readers. Furthermore, as described by Fuchs et al. (2001), understanding text and relating it to prior knowledge in the domain of the text may help readers correctly anticipate words in connected text that they might struggle with if they were presented out of context. As suggested by Young, Bowers, and MacKinnon (1996), this process may play a particular role in poor readers' gains in reading speed, freeing resources for comprehension and permitting proper phrasing and expressiveness to emerge as by-products of the dual improvements in word reading efficiency and comprehension. Weighing in on the debate about the nature of the relationship between fluency and comprehension, Paris, Carpenter, Paris, and Hamilton (2005) cautioned against viewing fluency as necessary or sufficient for comprehension because of the multiple shared processes that may account for relations between fluency and comprehension, such as vocabulary, syntactic knowledge, and background knowledge.

### Research Questions

The present study addressed four questions regarding the relationship between reading fluency and comprehension:

1. To what extent does each type of fluency—word, syntactic, and passage—correlate with reading comprehension when the other types of fluency, inferencing, and prior knowledge are statistically controlled?
2. To what extent is the association of each type of fluency with reading comprehension mediated by inferencing and prior knowledge?
3. To what extent does each type of fluency correlate with reading comprehension when the other types of fluency are statistically controlled?
4. To what extent does fluency predict changes in comprehension over a 12-week period, and to what extent does reading comprehension predict changes in fluency over the same length of time?

### Method

#### Participants

The participants in the present study were 278 fifth-grade students from 13 classrooms in three schools. The schools were located in a small city in a mid-Atlantic state. As shown in Table 1, the sample was representative of the school district in terms of the percentage of male and female students and the percentages of students receiving English as a Second Language (ESL) instruction, special education services, and free and reduced-price meals (FARMS). The students' mean grade equivalency score on the Gates-MacGinitie Reading Test, taken near the beginning of the school year, was 5.87 ( $SD = 3.17$ ). It should be noted that the sample included students reading several years below to several years above grade level.

Table 1  
*Demographic Characteristics of Students in the Sample and in the School District*

Characteristic	Sample (%)	District (%)
Gender		
Male	49.6	51.2
Female	50.4	48.8
Ethnicity		
African American	20.5	10.8
Asian	2.9	3.8
Caucasian	65.2	79.1
Hispanic	8.8	6.0
Other	2.6	0.3
ESL	4.8	5.4
Special education	9.2	11.6
FARMS		18.1

*Note.* The district percentages for gender and ethnicity represent students at the elementary school, middle school, and high school levels combined; the English as a Second Language (ESL), special education, and free and reduced-price meals (FARMS) represent elementary school students only.

### Measures

*Rationale for measurement design.* Three measures of fluency and single measures of reading comprehension, inferencing, and background knowledge were used. As detailed below, the reading comprehension and inferencing assessments, as well as two of three fluency measures, shared a partially common text base. Although this methodological approach may raise questions about measurement independence, it enables specification of the conditions under which different aspects of fluency relate to comprehension. With this approach, we expected the variables under study to show strong relationships, or at least relationships stronger than those that would be obtained if the measures were based on entirely different texts. In this way, then, text characteristics were controlled across the reading tasks, which could otherwise differentially influence the construct being measured.

*Gates-MacGinitie Reading Test (GMRT).* GMRT Forms S and T (comprehension tests) were used. This test was administered to all students in late August and mid-December. At the first test point, students were assigned to Level 4, 5, or 6 of Form S of the test on the basis of teacher judgments of their general reading ability and school records. At the second test point, students were reassigned to the same test levels of Form T unless they had scored below or above a predetermined cutoff point at the first test point. The extended scale scores were used in analyses because the raw scores are subject to skew. Also, the extended scale scores fulfill the assumption of equal interval scaling more adequately than raw scores because they normalize the raw scores, especially at the ends of the continuum. Furthermore, the meaning of extended scale scores is the same, regardless of the test level administered (MacGinitie, MacGinitie, Maria, & Dreyer, 2000).

*Inferencing assessment.* Our inferencing measure was designed to assess the skill of readers in recognizing implicit information in text. That is, an inference is a connection made between elements of a text based on the text itself and the reader's background knowledge; this definition is similar to the definition of bridging inferences used by Hannon and Daneman (2001) and Kintsch (1998). In addition, like Hannon and Daneman, true-false

items based on the stimulus texts were used to assess inferencing skill.

Three levels of the inferencing assessment were created to correspond with the three levels of the GMRT that were used at Time 1. From the first half of each level-form combination of the GMRT comprehension subtest, two passages (one narrative and one expository) were selected. These passages, which are referred to below as the *stimulus texts*, provided the text base for the items on the inferencing assessment and for two of our fluency measures (the Word Recognition Assessment and the Passage Oral Reading Assessment). Students received inferencing and fluency tests that corresponded with the level of the comprehension test they received.

On each level of the inferencing assessment, the two stimulus texts from the GMRT were presented, each followed by six true-false items. One item in each set of six was constructed to measure literal comprehension or very low level inferencing, whereas the other five items were constructed to measure middle- to high-level inferencing. For instance, an item could require processing only one or two sentences, a single paragraph, or the entire passage. Before completing the assessment, students completed two practice items that were based on a sample passage. Cronbach's alpha was .52.

*Background knowledge assessment.* The background knowledge measure assessed knowledge of ecological concepts. This measure was considered a proxy for a test of more general knowledge, based on the assumption that knowledge of one topic area would predict knowledge of other topics. Nineteen multiple-choice items were constructed; each item consisted of a stem and four alternative words or phrases to complete the stem. The Cronbach's alpha value obtained for this measure was .63. In addition, a correlation of .71 was observed for test-retest scores from a quarter of the sample, who took the test again 3 months later.

*Word recognition assessment.* This assessment measured fluency at the word level, defined in this study as how quickly students could correctly identify individual words presented in a list. Two word lists were created that corresponded with each stimulus text by first placing all unique words from each text in order by length, with the exception that proper nouns were placed at the end of each list. The full list was then divided in half, into A and B forms, by alternately placing the ordered words on separate lists. Students received either the A or the B list that corresponded to one of the stimulus passages for their assigned level, using a counterbalancing system detailed below in the *Procedure* section. The lists varied in length from 28 to 44 words.

The directions for the Word Recognition Assessment (WRA), which was individually administered by research team members, were as follows:

I'm going to give you a list of words to read out loud. You'll begin at the top left of the list, and read down each column. You may use your finger to help you keep your place if you would like. Read the words as quickly as you can without making mistakes. If you come to a word that you don't know, skip it and go to the next word. Continue reading until I ask you to stop or until you finish the entire list. I'm going to use a stopwatch to see how long it takes you. Do you have any questions?

After reading these directions aloud, the administrator gave the student a practice list consisting of six words and then the test list.

During the testing phase, the administrator marked any words that the student read incorrectly or omitted and used a stopwatch to record the number of seconds that it took the student to read the full list. The WRA was scored by calculating the number of words read correctly per minute, termed *word reading speed* in the present study. Moreover, word accuracy was determined by calculating the percentage of words each student read correctly. However, consideration of the high mean for percentage correct (91.6), in combination with the fact that the standard deviation for words correct per minute was nearly twice that for percentage correct (26.0 vs. 13.5) led to the decision to use only words correct per minute in the analyses.

Reliability for the WRA was determined by calculating the test-retest correlation for word reading speed for a quarter of the original sample, who were retested 3 months later with word lists based on different passages. This test-retest correlation was .72.

*Woodcock-Johnson III Reading Fluency Test.* Performance on the Reading Fluency Test from the Woodcock-Johnson III (WJ-III) Diagnostic Reading Battery measured fluency at the syntactic level, defined in this study as accuracy and speed in processing phrase and sentence units of text. This test consisted of 98 simple sentences primarily describing common animals and objects. Students were directed to silently read as many of the sentences as they could within 3 min, circling *Y* for "yes" or *N* for "no" after each sentence, depending on whether it was true or false. Scores on the test equal the number of correct responses minus the number of incorrect responses. The raw score associated with a grade equivalency of 5.0 is 43. The internal consistency coefficient for age 10 is .90, and the 1-year test-retest reliability for students who first take the test at ages 8–10 is .78 (Schrank, Mather, & Woodcock, 2004). The publisher's directions for individual test administration were adapted for administration on a classroom basis by each classroom teacher with the assistance of a research team member.

*Passage Oral Reading Assessment (PORA).* This assessment measured fluency at the passage level, defined in this study as expressive oral reading of expository or narrative text. Furthermore, it provided data for an alternate measure of syntactic processing.

In the PORA, students' oral rendering of an intact passage, either one of the two passages selected as stimulus texts from the GMRT, was recorded with a Sony digital recorder. The passage that each student was asked to read consisted of the same words as those on the list that the student was given for the WRA. The directions for the PORA were the following:

I'm going to give you a passage to read out loud. Read it as expressively as you can. It's important to make it sound interesting. You don't have to read it quickly. If you come to a word that you don't know, skip it and go to the next word. Continue reading until I ask you to stop or until you finish the passage.

An oral reading fluency rubric was developed to evaluate each student's passage reading on five dimensions. Students were rated on each dimension on a scale ranging from 1 (*very weak*) to 4 (*very strong*). Only two of these dimensions were used in the analyses in the present study: passage expressiveness, which served as our measure of passage-level fluency, and phrasing, which served as our alternate measure of syntactic-level fluency. The other three dimensions evaluated included pace, smoothness, and word expressiveness.

On the passage expressiveness dimension, students' scores were based on their oral interpretation of the passage as a whole, including the appropriateness and consistency of the mood or tone created by their oral reading. If their reading evoked no mood or tone, they received a 1. If approximately a quarter of the passage was interpreted expressively, they received a 2. If half to three quarters of the passage was read with a consistent tone, they received a 3, and if they read the whole or nearly the whole passage in an expressive manner that created a mood or tone that seemed in accord with the author's intention, they received a 4.

The scale for phrasing was drawn largely from the National Assessment of Educational Progress fluency rubric (Pinnell et al., 1995). On this dimension, students receive a 1 if they read primarily word by word, a 2 if they read primarily in two-word phrases, a 3 if they read primarily in three- or four-word phrases or in run-on sentences, or a 4 if they read primarily in larger, meaningful units.

Three judges received training in using the fluency coding rubric and then independently rated the readings of 16 students on the five dimensions. Median agreement for exact scores was 50%, and median agreement for adjacent scores was 96%. A median correlation of .70 was obtained for the ratings of the three judges. To further examine interrater reliability, all ratings of 4 on the original scale were recoded as 3s. On this collapsed scale, exact agreement for two judges (who rated the remainder of the recordings) was 79%.

In sum, the reliabilities of the measures were generally moderate. For background knowledge, word recognition speed, and WJ-III syntactic processing fluency, the test-retest reliabilities ranged from .71 to .79. The test-retest reliability of the GMRT reading comprehension is known to exceed .90. Relatively low reliability was observed for the measure of inferencing, with the alpha of .52 showing error in this measure. Inferencing correlated with GMRT reading comprehension at .57, whereas word recognition speed correlated with it at .65, indicating that inferencing had association with other variables. Although its lower reliability placed limits on the contribution of inferencing to the dependent variable, inferencing retained a statistically significant level of association with comprehension in the full regression model.

## Procedure

At Time 1 (the beginning of the school year), all students in the sample completed the following assessments in the following order: (a) GMRT comprehension subtest, (b) WJ-III Reading Fluency subtest, (c) background knowledge, and (d) inferencing. These assessments were administered by the classroom teacher during regular class time, taking 90 min total across 2 days. In addition, approximately 12 students per classroom completed the WRA and PORA. The students completing these two assessments included all those predesignated as struggling readers (i.e., those assigned to Level 4 of the GMRT because they were deemed to be reading below grade level) and a random sample of at- and above-grade readers (i.e., those assigned to Level 5 or 6 of the GMRT) so that a total of 12 students per class were preselected (however, because of absences, sometimes fewer than 12 students per class were actually tested).

The sample who completed the additional fluency measures had a mean reading comprehension grade equivalent of 5.34 ( $SD =$

3.13). This differed from the total original sample, which had a mean reading comprehension grade equivalent of 5.87 ( $SD = 3.17$ ). Thus, the sample generalizes to students in Grade 5 who are slightly below the Grade 5 students in those schools. The rationale for the selection was that the resources were not available to test all 278 students individually in oral reading fluency within the time allowed for testing by the school. In addition, there was a need to represent the lower achieving readers fully to allow relatively strong inferences to be made about variables that distinguish lower and higher comprehenders in Grade 5.

Research assistants individually administered the WRA and PORA outside of the classroom. Within the three test levels (4, 5, and 6), the order of testing (WRA or PORA first) and the passage presented for the PORA (the expository or narrative passage) were counterbalanced, along with the presentation of the corresponding word list (A or B) for the passage each student was asked to read aloud. The individual testing sessions typically took less than 5 min.

At Time 2, students completed the GMRT comprehension test. The WJ-III Reading Fluency Test was also administered at this time.

## Results

### Variable Information

The following variables from Time 1 were used in the analyses: word recognition speed, syntactic processing, phrasing, passage-level processing, background knowledge, inferencing, and reading comprehension. In the last analysis, syntactic processing and reading comprehension from Time 2 were also used. All variables had distributions within acceptable ranges of normality.

### Descriptive and Correlational Statistics

Table 2 presents the pairwise correlations among all variables included in the analyses. As seen in this table, reading comprehension at Time 1 correlated moderately to strongly with all other Time 1 variables (median  $r = .67$ ), indicating that further analyses of the relationships among these variables were warranted. Specifically, hierarchical regression analyses were planned to partition the shared variance among the variables. In addition, syntactic processing at Time 1 strongly correlated with reading comprehension

at Time 2, as did reading comprehension at Time 1 with syntactic processing at Time 2, indicating that the relationships among these variables might also be explored through hierarchical regression analyses. Table 3 shows the mean, standard deviation, and sample size associated with each variable.

### Question 1

Our first analysis investigated the extent to which each type of fluency—word, syntactic, and passage—correlated with reading comprehension when the other types of fluency and background knowledge and inferencing were statistically controlled. Reading comprehension at Time 1 was entered as the dependent variable in a hierarchical regression with the following independent variables from Time 1 entered as separate steps in this order: background knowledge, inferencing, word recognition speed, syntactic processing, and passage-level processing. As seen in Table 4, which summarizes the statistical output of the five models obtained, the addition of each variable added significantly to the amount of variance accounted for in reading comprehension. Background knowledge alone explained 50% of the variance in reading comprehension, with inferencing accounting for an additional 8%. Word reading speed added another 10% to the explained variance; syntactic processing added 5%; and last, passage-level processing added 2%. Thus, altogether, the five independent variables accounted for 75% of the variance in reading comprehension. Fur-

thermore, each variable significantly predicted reading comprehension in the final model.

In addition, as seen in Table 4, the betas associated with background knowledge decreased as the number of variables included in the regression models increased. For example, the beta associated with background knowledge in Model 2 was .59 and decreased to .45 when word reading speed was added in Model 3, suggesting that background knowledge was partly associated with word reading speed. Similarly, the betas associated with inferencing, word reading speed, and syntactic processing decreased but remained significant in each subsequent model, providing further indication of both the relatedness and the distinctiveness of the variables.

Question 2

We conducted a second hierarchical regression analysis to analyze the extent to which the association of fluency variables with reading comprehension was mediated by the cognitive variables of inferencing and background knowledge. The dependent variable was reading comprehension, and the independent variables were entered in the following order: word recognition speed, inferencing, background knowledge, syntactic processing, and passage-level processing. The statistical output contained five models, summarized in Table 5.

The first of the five models showed that word recognition speed and reading comprehension were strongly related. The second

model showed that word recognition speed was associated with reading comprehension and inferencing was associated with reading comprehension when each was controlled for the other in the equation. The decrease in association of word recognition speed and reading comprehension from Model 1 to Model 2 indicated that word recognition speed shared variance with inferencing. Note also that word recognition speed retained a unique association with reading comprehension of .54, even after accounting for its association with inferencing.

The third model showed that word recognition speed was also associated with background knowledge. In Model 3, the association of word recognition speed with reading comprehension decreased, which suggested that the effects of word recognition speed on reading comprehension were additionally mediated by background knowledge. Notice that for Model 3, background knowledge was significantly associated with reading comprehension, with its final beta of .45.

The fourth model indicated that syntactic processing was significantly associated with reading comprehension. A reduction in the association of inferencing and background knowledge with reading comprehension from Model 3 to Model 4 was evident. However, all of the contributions of syntactic processing were not mediated because this variable's final beta retained statistical significance.

The fifth model showed that passage-level processing in oral reading shared variance with all of the other variables. Each of the

variables, including word recognition speed, inferencing, background knowledge, and syntactic processing decreased in strength from Model 4 to Model 5. Yet none of these variables was reduced to statistical insignificance, and passage-level processing retained a statistically significant final beta. Note that for Model 5,  $R = .87$  and  $R^2 = .75$  ( $p < .01$ ).

### Question 3

The next hierarchical regression analysis examined the extent to which each type of fluency—word, syntactic, and passage—correlated with reading comprehension when the other types of fluency were statistically controlled. This analysis served partially as a check on the first analysis in that a different variable (phrasing) was used as a measure of fluency at the syntactic level. Reading comprehension at Time 1 was again entered as the dependent variable, with Time 1 word reading speed, phrasing, and passage-level processing entered in subsequent, separate steps. As seen in Table 6, word reading speed alone explained 43% of the variance in reading comprehension. Phrasing explained an additional 10% of the variance, and passage-level processing explained an additional 4% of the variance beyond that. In the final model, each fluency variable was significantly associated with comprehension.

### Question 4

Finally, hierarchical regression analyses were conducted to address the extent to which fluency predicted change in comprehension over a 12-week period and the extent to which reading comprehension was associated with change in fluency over the same length of time.

In the first analysis, Time 2 reading comprehension was the dependent variable, Time 1 reading comprehension was entered as the first independent variable as an autoregressor, and Time 1 syntactic processing was entered in the second step as a measure of fluency. The output, summarized in Table 7, indicated that Time 1 syntactic processing significantly explained Time 2 reading comprehension, controlling for Time 1 reading comprehension. In the second analysis, Time 2 syntactic processing was the dependent variable, Time 1 syntactic processing was entered as the first independent variable as an autoregressor, and Time 1 reading comprehension was entered in the second step of the regression. The output, which is also shown in Table 7, indicated that Time 1

reading comprehension explained significant variance in Time 2 syntactic processing, controlling for Time 1 syntactic processing.

The use of the autoregressor in these analyses permits the inference that the predictor of syntactic fluency was associated with changes (in this case, increases) in reading comprehension. This is more suggestive of causality than a regression with no autoregressor, in which case the inference is that the predictor was associated with the level of posttest reading comprehension (De Jong & van der Leij, 2002; Gollob & Reichardt, 1987). The same argument holds for the reversed order of testing. That is, with the autoregressor present, pretest comprehension was associated with changes in the syntactic fluency measure. The reciprocity of fluency and comprehension was evaluated for the syntactic measure only as a result of limitations in space available to report the findings. The rationale for using the syntactic measure was that it is a commercially available test and its internal consistency reliability was relatively high.

### Discussion

One of the major findings of the present study was that each of the three types of fluency—at the word, syntactic, and passage levels—related individually to performance on a standardized reading comprehension test in a sample of fifth graders heterogeneous in general reading ability. In other words, the students who demonstrated the highest performances in reading comprehension also displayed (a) fast recognition of isolated words; (b) adeptness in processing phrases and sentences as syntactic units while engaged in oral and silent reading; and (c) appropriate, consistent expression when reading stories and information text out loud. Notably, the relationships between each type of fluency and reading comprehension were significant, both when only the fluency variables were used as predictors in the model and when background knowledge and inferencing skill were included as controls.

Previous studies have reported the association of fluency and comprehension using one measure of fluency, which is usually word recognition speed (De Jong & van der Leij, 2002; Schwanenflugel et al., 2004). However, there remains unexplained variance in reading comprehension in those studies. The present findings suggest that some of the unexplained variance in reading comprehension may be attributed to the two additional forms of fluency that were observed (syntactic fluency and passage level).

The associations between the reading fluency variables and reading comprehension were partially mediated by the cognitive

variables of inferencing and background knowledge. The results may be viewed as evidence of an automaticity effect for word recognition speed, as well as an automaticity-like effect for syntactic processing; that is, faster speeds of word recognition and higher performance on the syntactic processing measure (the WJ-III measure of fluency, which is speeded) may indicate that fewer cognitive resources are needed for those activities. Hence, more cognitive resources are available for inferencing and using background knowledge in reading comprehension. The results also indicated that better performance on the passage-level processing fluency measure was linked with better performance on the cognitive measures and two other fluency measures. These links suggest that passage-level fluency may be associated with a greater allocation of cognitive resources to comprehension, but also that passage-level processing is dependent on language processes similar to those involved in inferencing and using background knowledge to understand text.

Last, reading fluency at the beginning of the study predicted growth in comprehension 12 weeks later. In addition, comprehension at the beginning of the study predicted growth in fluency 12 weeks later. In other words, reading comprehension and reading fluency appeared to have a bidirectional relationship when fluency was measured at the syntactic level. Several investigators have recommended that such longitudinal data with the inclusion of an autoregressor are strongly indicative of causal relations (De Jong & van der Leij, 2002; Gollob & Reichardt, 1987); however, previous studies have used students in Grades 1–3 (De Jong & van der Leij, 2002) or have not examined syntactic processing fluency (Jenkins et al., 2003b) with longitudinal data.

The present findings are consistent with automaticity theory's assertion that fast, accurate word recognition frees cognitive resources for reading comprehension (LaBerge & Samuels, 1974). This is suggested by the strong relationships observed in this research between word recognition and reading comprehension performance, the primary type of evidence presented as support by others (e.g., Jenkins et al., 2003b; McCormick & Samuels, 1979).

The findings are also consistent with research suggesting that fluency and comprehension are linked not only because they both involve processing individual words, but also because they both involve processing of syntactic units (Kuhn & Stahl, 2003; Young & Bowers, 1995). We found that two measures of syntactic processing, one involving fast, accurate processing of simple sentences and the other assessing whether students read aloud with proper phrase and sentences units, predicted reading comprehension when controlling for word recognition speed. In addition, the present results extend our current understanding of the relationship between fluency at the syntactic level and reading comprehension, as we also found evidence for an automaticity-like effect for syntactic processing. These findings, on the other hand, appear to be inconsistent with Schwanenflugel et al.'s (2004) findings that prosody in young children's oral reading, measured in part as whether the readers marked phrases and sentences with pauses of appropriate length, did not correlate with reading comprehension after word recognition automaticity was controlled. One reason may be that Schwanenflugel et al.'s (2004) measure of prosody was based on reading a passage that was not part of their comprehension measure, whereas in this study the passage that each student read aloud and on which our phrasing measure was based also appeared on the reading comprehension test that the student received. Thus, in this study the identity of text in the oral reading and the comprehension tasks made it likely that the text features used in fluency might also be used in comprehension.

The present study extended previous research on the links between fluency and comprehension by examining fluency at the whole-passage level. Although some holistic fluency rubrics already existed that give attention to overall expressiveness in combination with the speed and accuracy components of fluency (Pinnell et al., 1995; Zutell & Rasinski, 1991), in this research a new rating scale was created solely for assessing the student's expressive interpretation of the passage. To receive the highest score on this scale, students had to create a tone or mood in their oral rendering of the passage through application of proper stress,

pitch changes, pause structure, and rhythm that was consistent with the author's apparent intent, and they had to maintain this expressive interpretation for the entire length of the passage.

Students who scored high on reading comprehension also tended to receive high scores for expressiveness at the passage level, which indicates that similar types of processing were involved in these tasks. More specifically, this relationship may be an indicator that these students were accurately representing the macrostructure features of the passages they were asked to read aloud. Although having awareness of the macrostructure of both stories and information text has been linked to better reading comprehension (Meyer, 1999; Meyer et al., 1989, 2002; Olson & Gee, 1988), such awareness has not previously been investigated in relation to fluency.

The present study does not attempt to provide direct evidence that students who scored higher on passage expressiveness indeed possessed accurate macrostructures of the passages they read aloud. However, awareness of the macrostructure may explain the relationship between passage expressiveness and reading comprehension that was found after controlling for fluency at the word and syntactic levels along with controlling for other cognitive variables. For example, to illustrate how macrostructure awareness could be manifest through oral reading fluency, consider a child who encounters an information text with the problem-solution structure, for example a text that presents destruction of the rainforests as a problem and explores what can be done to address this problem (Meyer et al., 1989). If the child recognizes that the text possesses this structure, he or she may be more inclined to read the solution section of the passage with a persuasive, excited tone. The child may also place strong emphasis on words that signal the solution (e.g., *answer, to solve these problems*; Meyer et al., 1989).

Finally, the results involving the directionality of the relationship between fluency and comprehension support the idea that these two reading skills have a reciprocally predictive relationship (Stecker et al., 1998). Such findings could be interpreted as support either for the notion that fluency facilitates comprehension growth, in line with automaticity theory, and that comprehension facilitates fluency growth through top-down processes (Rumelhart, 1994) or for joint causation of fluency and comprehension by one or more other factors. The joint causation scenario, it should be noted, aligns with the contention of Paris and colleagues (Paris & Paris, 2001; Paris et al., 2005) that variables such as vocabulary knowledge and motivation may account for high correlations between performance on fluency and comprehension measures. These bivariate correlations support the suggestions of Jenkins et al. (2003b) that comprehension and fluency performances may be linked because they involve similar language processes, perhaps syntactic as well as semantic. Thus, fluency and comprehension skills should become more similar over time up to the age of approximately 10–12 years.

Although the preceding discussion focuses on the contributions of the present study, it is also important to recognize the study's potential limitations. One concern may be multicollinearity because the word recognition and oral reading tasks were developed from the same passages. Furthermore, the passage that each student read aloud was one of the two passages that appeared on the inferencing tests that they received and one of the several passages that appeared on the GMRT. However, we deemed it important to link the measures in this way because of how much the expressive

components of fluency and comprehension may vary from text to text because of differences in the text's grammatical complexity or in the reader's interest in and familiarity with the text. In other words, there seems little reason to expect that expressiveness and comprehension based on very dissimilar texts would be highly related. Furthermore, the bivariate correlations among the variables used in the present study (see Table 1) should assuage the multicollinearity concern; for instance, word recognition speed and passage-level processing had a correlation of .57, which is certainly strong but not so high as to indicate that these measures were assessing the same processes.

Two other limitations of the present study should be mentioned. First, the Cronbach's alpha values for both the inferencing and the background knowledge assessments were lower than the desirable value of .70 or higher. Second, although the regression models accounted for large percentages of the variance in comprehension, important variables may have been left out of the design and thus the analyses. Namely, as mentioned above, Paris and colleagues (Paris & Paris, 2001; Paris et al., 2005) have suggested that vocabulary knowledge and motivation might account considerably for the relations between fluency and comprehension.

In conclusion, the findings of the present study support the multidimensionality of fluency and suggest that future research might examine whether the various levels have different relationships to comprehension across different grade levels. For example, it is possible that word-level fluency is associated with comprehension at primary Grades 1–3, whereas passage-level fluency is associated with comprehension at intermediate Grades 4–6. In addition, future research might examine how the multiple levels of fluency and comprehension are related when motivation is also assessed. Last, assessment of fluency at multiple levels may be particularly important in reading intervention research, as word-, syntactic-, and passage-level fluency may be differentially sensitive to alternative interventions.

### Members of Underrepresented Groups: Reviewers for Journal Manuscripts Wanted

If you are interested in reviewing manuscripts for APA journals, the APA Publications and Communications Board would like to invite your participation. Manuscript reviewers are vital to the publications process. As a reviewer, you would gain valuable experience in publishing. The P&C Board is particularly interested in encouraging members of underrepresented groups to participate more in this process.

If you are interested in reviewing manuscripts, please write to the address below. Please note the following important points:

- To be selected as a reviewer, you must have published articles in peer-reviewed journals. The experience of publishing provides a reviewer with the basis for preparing a thorough, objective review.
- To be selected, it is critical to be a regular reader of the five to six empirical journals that are most central to the area or journal for which you would like to review. Current knowledge of recently published research provides a reviewer with the knowledge base to evaluate a new submission within the context of existing research.
- To select the appropriate reviewers for each manuscript, the editor needs detailed information. Please include with your letter your vita. In the letter, please identify which APA journal(s) you are interested in, and describe your area of expertise. Be as specific as possible. For example, "social psychology" is not sufficient—you would need to specify "social cognition" or "attitude change" as well.
- Reviewing a manuscript takes time (1–4 hours per manuscript reviewed). If you are selected to review a manuscript, be prepared to invest the necessary time to evaluate the manuscript thoroughly.

Write to Journals Office, American Psychological Association, 750 First Street, NE, Washington, DC 20002-4242.

# Native Language Proficiency, English Literacy, Academic Achievement, and Occupational Attainment in Limited-English-Proficient Students: A Latent Growth Modeling Perspective

R. Sergio Guglielmi  
Lake Forest College

The hypothesis that native language (L1) proficiency promotes English acquisition and overall academic achievement, a key theoretical assumption underlying bilingual education, was tested using latent growth modeling of data from 899 limited-English-proficient (LEP) eighth graders who were followed for 12 years in the National Education Longitudinal Study (NELS:88/2000). A model in which L1 proficiency predicted English (L2) reading ability, which in turn predicted high school achievement and distal educational/occupational attainment, fit the data well for the full LEP sample and a Hispanic subsample. In Hispanics, the model explained 24.1%, 7.4%, 29.4%, and 46.3% of the variance in initial English reading level, English reading growth, high school achievement, and post-high school attainment, respectively. Model fit for an Asian subsample, however, was poor. Possible reasons for lack of group invariance include cultural differences in construct conceptualization, greater linguistic and cultural heterogeneity within the Asian subgroup, and cross-language transfer difficulties when L1 and L2 lack a shared alphabetic structure. At least for Hispanic LEP students, this study's results establish the theoretical foundation for exploring the effectiveness of specific educational interventions.

**Keywords:** bilingual education, English language learner, latent growth modeling, multitrait-multimethod, literacy

The U.S. Department of Education (Kindler, 2002) estimates that in 2000–2001 more than 4.5 million public school students (preK–12) in the United States were identified as limited-English-proficient (LEP),<sup>1</sup> and by the year 2030, this number is projected to grow to 40% of the school-age population (Thomas & Collier, 2002). How our schools should respond to the needs of the rapidly expanding LEP population has been the object of a vigorous national debate.

In *Lau v. Nichols* (1974), the U.S. Supreme Court recognized that LEP students would be locked out of the educational system unless schools developed instructional programs that would give them access to a meaningful education despite the language barrier. Although the Court prescribed action, it gave local school

districts the power to decide which particular educational programs to institute. Since then, legislators, educators, academicians, policymakers, and advocacy groups have argued the relative merits of various approaches to educating the growing LEP population. The controversy over the effectiveness of bilingual education has reached especially harsh tones. Fundamentally, the debate centers on the value of two different pedagogical models. One approach is full English immersion. In these cases, the language barrier problem is often addressed by placing LEP students in English-as-a-second-language (ESL) classes, where they receive instruction in the English language skills necessary to operate in a mainstream classroom. On the other side of the debate, proponents of bilingual education advocate academic instruction in both the students' first language (L1) and in English, the second language (L2), with the amount of time spent in L1 instruction decreasing progressively over the course of a few years (early exit programs) or several years (late exit programs).

In the last several years, bilingual education has come under attack, and in some cases (e.g., the passage of Proposition 227 in California and of Proposition 203 in Arizona), its continued existence has been threatened. Unfortunately, judgments about the effectiveness of bilingual education (for or against) are often driven more by sociopolitical motivations than by an objective evaluation of the scientific evidence. A substantial literature on the

<sup>1</sup> Although the term English language learner (ELL) has become preferable in the last few years, I will continue to refer to these students as LEP in order to maintain consistency with the terminology most often adopted in legislative documents, in government publications, and in the data set used in the present investigation.

relative value of bilingual versus English immersion instructional approaches is indeed available and has been periodically reviewed (e.g., Rossell & Baker, 1996; Slavin & Cheung, 2003). The methodological difficulties that plague the empirical research, together with the fact that the available evidence does not point incontrovertibly in one direction, however, have left considerable room for political agendas to shape the debate.

Generally speaking, the quality of the research on either side of the controversy is unimpressive. A tolerance, if not predilection, for descriptive and qualitative analyses and for methodological designs that disregard elementary principles of scientific inquiry, has generated findings that are frequently disseminated through outlets that elude the peer review process.

Among other serious weaknesses, it is often difficult to determine the nature of the educational programs to which students were actually exposed. School programs for LEP students may be called bilingual by parents, teachers, or administrators simply because they are received by language-minority students, even when in actuality they are English-only programs, such as structured English immersion or ESL pullout (Rossell, 2003). Moreover, even when a program does indeed have a native language instruction component, calling it bilingual provides little information about its key characteristics. The bilingual programs actually implemented vary tremendously, ranging from minimal L1 instruction and early exit to extensive L1 instruction and late exit (August & Hakuta, 1997; Slavin & Cheung, 2003; Thomas & Collier, 2002).

One way out of the political and scholarly impasse is to shift the research focus away from programs labels and onto specific and definable program components in an effort to identify effective instructional methods, regardless of whether those methods are embedded in bilingual or in English immersion programs (August & Hakuta, 1997, 1998; Slavin & Cheung, 2003). A related approach is to test specific predictions generated from bilingual education theory; without confirmation of such predictions, the theory's validity cannot be established (Cummins, 1999). An important advantage of testing specific hypotheses and program components is that once the key elements of successful outcomes are identified and once the causal structure that specifies the relation among those elements is determined, effective educational programs can be constructed more efficiently and, hopefully, less controversially.

Bilingual education theory allows the prediction that proficiency in one's native language (however achieved) contributes to the development of L2 literacy and ultimately to satisfactory academic achievement in LEP students, regardless of the particular instructional program in which they may have been placed. Some indirect support for this proposition comes from cross-language transfer research.

Additive bilingualism (i.e., the development of fluency in both L1 and L2) has been associated with a variety of general cognitive advantages in the areas of divergent thinking, nonverbal reasoning, concept formation, metalinguistic awareness, creativity, and cognitive flexibility (August & Hakuta, 1998; Portes & Hao, 1998). Positive transfer of literacy skills across languages has also been repeatedly demonstrated (Geva & Siegel, 2000; Holm & Dodd, 1996; Verhoeven, 1994). With respect to the specific cognitive processes involved in biliteracy development, Durgunoğlu (2002), among others, distinguished between (a) language-independent metacognitive and metalinguistic components, which are believed to be universal and, once acquired, support literacy development across different languages and (b) language-specific components,

which reflect instead the particular features of a given language (e.g., its orthographic structure) and may facilitate or hinder the development of literacy in a second language. Phonological awareness is a metalinguistic skill that has been the object of intense research attention, perhaps because of its critical importance in the development of reading. Experimental psycholinguistic research has provided consistent and convincing evidence for cross-language transfer of phonological awareness (e.g., Bialystok, Luk, & Kwan, 2005; Dickinson, McCabe, Clark-Chiarelli, & Wolf, 2004; Durgunoğlu, Nagy, & Hancin-Bhatt, 1993; Gottardo, Yan, Siegel, & Wade-Woolley, 2001).

Although this research indicates that literacy in the first language facilitates reading acquisition in the second language, these conclusions require some qualification. Contrary findings by Gottardo et al. (2001) notwithstanding, several recent studies have reported that phonological awareness and reading skills transfer only, or at least more easily, when L1 shares with English an alphabetic structure (Akamatsu, 2003; Bialystok et al., 2005; Wang & Koda, 2005; Wang, Koda, & Perfetti, 2003). In these studies, participants who spoke an alphabetic first language (i.e., Spanish, Korean, Persian, or Hebrew) exhibited cross-language transfer to English to a much greater degree than did speakers of nonalphabetic first languages (i.e., Chinese or Japanese).

Furthermore, the findings of the literature on cross-linguistic effects come from laboratory research in which participants were exposed to experimental tasks (such as phoneme substitution, phoneme segmentation, semantic category judgment) that arguably bear little resemblance to the tasks faced by LEP students in the classroom. Whether those findings generalize to more complex and more ecologically valid settings and whether the established cross-linguistic transfer effects have a positive and lasting influence on important educational outcomes (e.g., grades, graduation rates) remain open questions. The goal of the present research was to help elucidate these important unanswered issues.

### The Present Study

On the basis of existing research and theory, one can posit a model that specifies the pathways through which bilingual education might exert its effects. According to this model, LEP students' postsecondary academic and occupational attainment is a function of earlier academic achievement, which depends, in large part, on the students' levels of English literacy, particularly as evidenced by reading ability. In turn, L2 literacy is expected to be predicted by proficiency in the native language. To my knowledge, this full model has not been tested in an LEP population, and whatever empirical support exists for individual components of the model comes either from laboratory research or from cross-sectional correlational data. A notable exception is a longitudinal study by Yeung, Marsh, and Suliman (2000) who found that L1 proficiency was unrelated to English scores and to academic achievement. In this study, however, the sample was composed of all students who reported using a language other than English, regardless of whether they were LEP. Moreover, high school and postsecondary outcomes were not included in the model. In the present study, I evaluated the adequacy of the full model by examining longitudinal data from the National Education Longitudinal Study of 1988 (NELS:88/2000) (Curtin, Ingels, Wu, & Heuer, 2002). In particu-

lar, three specific hypotheses, derived from the bilingual education framework, were tested.

1. Self-reported L1 proficiency will predict growth in L2 reading scores from Grade 8 to Grade 12. In view of the relative maturity of the sample, L1 → L2 facilitation effects, if found, would be more likely the result of language-specific mechanisms (e.g., utilization of surface structure similarity between the two languages, transfer of cognitive processing strategies) than the result of universal language structures and nonspecific metalinguistic mechanisms (e.g., cross-language transfer of phonological awareness). Thus, a corollary of the first hypothesis is that L1 proficiency will exhibit stronger L2 literacy facilitation effects in LEP students whose first language shares with English an alphabetic orthography.
2. Self-reported L2 proficiency (which includes students' perceptions of their ability to read in English) will be associated with both eighth grade initial reading scores and rate of reading progress over time.
3. L2 reading ability will predict both high school achievement and long-term educational and occupational end points assessed 8 years after high school graduation. In addition, L2 reading achievement scores will predict post-high school attainment indirectly through the mediation of the student's high school accomplishments.

Tests of these hypotheses required statistical control of socioeconomic status (SES) and of number of grades students completed outside the United States, two covariates expected to influence L1 and L2 proficiency, L2 reading growth, and long-term outcomes. Finally, if the adequacy of the model was confirmed on a full (mixed) sample of LEP students, the empirically established influence of orthographic structure on the extent of cross-linguistic transfer effects required that the model be tested for invariance across language-minority subgroups.

## Method

### *National Education Longitudinal Study (NELS:88/2000)*

NELS:88/2000 is a large-scale longitudinal investigation conducted by the National Center for Education Statistics (NCES). In 1988, more than 25,000 eighth-graders from a multistage, clustered, stratified national probability sample of more than 1,000 public and private schools were administered cognitive tests and questionnaires about their background, school experiences, goals, and attitudes. Supplementary information was obtained from the students' teachers, principals, and parents. The students were then surveyed four more times over a 12-year period (in 1990, 1992, 1994, and 2000), as they progressed through high school (or dropped out) and joined the workforce or went on to pursue postsecondary education. The sample was also "freshened" at each of the first two follow-ups to compensate for attrition and enable both cross-sectional and longitudinal comparisons. In addition, funds made available by the U.S. Office of Bilingual Education and Minority Languages Affairs permitted the oversampling of

Hispanic and Asian/Pacific Islander students. The result is a rich and multifaceted data set that includes thousands of variables and provides information on the lives of nearly 30,000 students, many of whom are not native English speakers. (Full documentation for the NELS:88/2000 project is available at <http://nces.ed.gov/surveys/nels88/>)

### *The LEP Sample*

Proper identification of LEP students from the larger NELS sample was obviously of key importance in this investigation. Although previous research has frequently relied on "bylep"—a composite indicator of base-year LEP status available in the NELS codebook—it is difficult not to share with other investigators dissatisfaction about the performance of this variable. Strang, Winglee, and Stunkard (for Westat, Inc., 1993), for example, looked carefully at the LEP selection issue and concluded that, among other shortcomings, "bylep" yields high rates of false-positive LEP identifications and fails to conform to the legislative definition of LEP as set forth in the Bilingual Education Act of 1988 (Title VII of P.L. 100-297). On the other hand, several elements of Strang et al.'s approach are problematic. Their definition did not incorporate all provisions of the Bilingual Education Act, they considered only language-assistance services received during the eighth grade (and not before) as evidence of a student's difficulty with English, their English proficiency measure cutoff value was not sufficiently stringent, and their definition did not include information from the third NELS wave (since that follow-up had not yet been completed).

Accordingly, an LEP selection measure that mirrors the requirements of the legislative definition was constructed for this study. Figure 1 summarizes the conditions that a student must meet in order to be identified as LEP according to the Bilingual Education Act of 1988.<sup>2</sup> Following a thorough search of the NELS data set (i.e., student, parent, and teacher questionnaires and students' high school transcripts), I extracted 97 variables that, as a group, could be used to assess all of the definitional elements diagrammed in Figure 1. Several of these variables related to the provision that the student's level of English proficiency be insufficient for the student to operate successfully in the classroom. One subset of these variables assessed the students' own perceptions of their ability to understand, speak, read, and write English. A 4-point response scale was provided, ranging from *very well* to *not at all* (although these options differed slightly across waves). Strang et al.'s (1993) LEP definition excluded only the *very well* responses; I excluded both the *very well* and *well* and accepted only the *not very well* and *not at all* responses as positive indicators of LEP status. The inclusion criteria used to select the present LEP sample follow step by step the decision scheme diagrammed in Figure 1. The appli-

<sup>2</sup> Omitted from the summary is the additional provision for "individuals who are American Indian and Alaska Natives and who come from environments where a language other than English has had a significant impact on their level of English language proficiency and who, by reason thereof, have sufficient difficulty speaking, reading, writing, or understanding the English language to deny such individuals the opportunity to learn successfully in classrooms where the language of instruction is English or to participate fully in our society." Such individuals would necessarily meet the other inclusion criteria and would therefore be part of the LEP sample already.

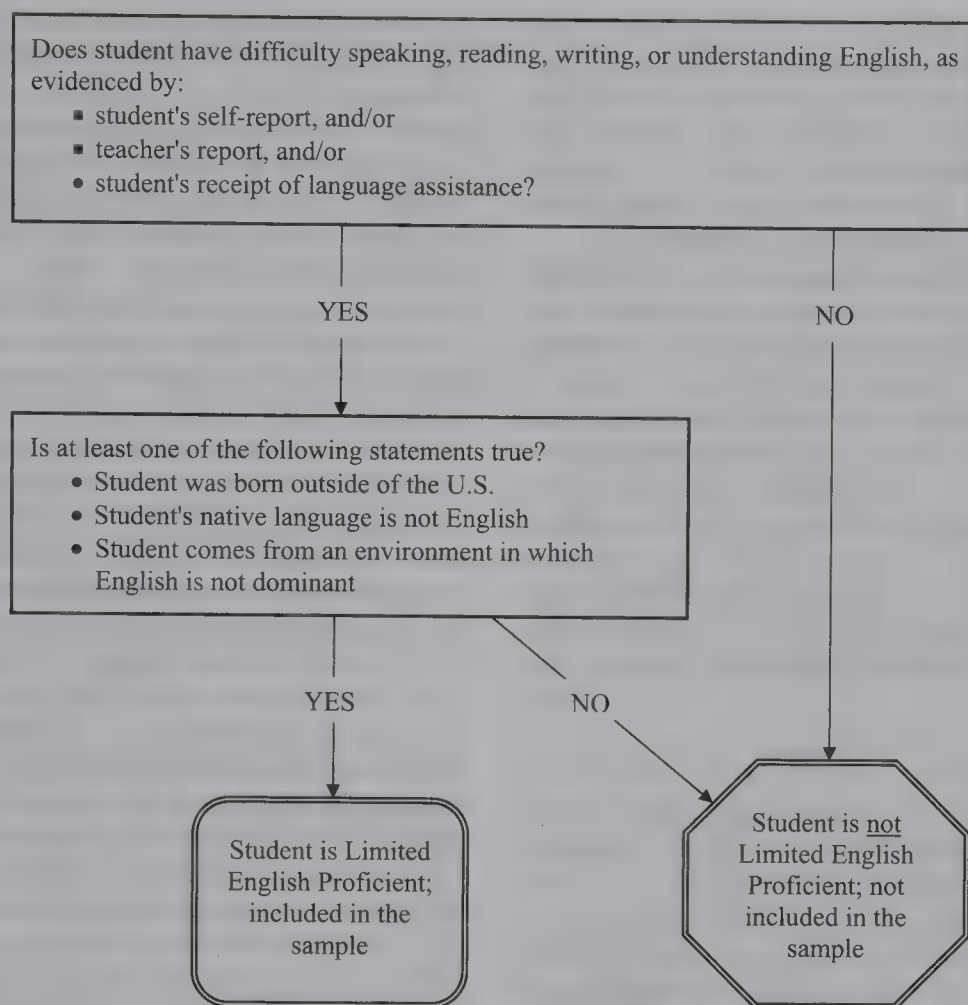

Figure 1. Decision rules for selection of limited-English-proficient sample.

cation of those criteria yielded an LEP sample of 2,997 students. A series of flags was then used to identify LEP responders who participated in all waves of the study and for whom transcript data were available. This process resulted in a final sample of 899 LEP participants.

### Measures

A restricted use data license for the NELS:88/2000 data set from the NCES Office of Data Security permitted access to transcript data and to other individually identifiable information. Many measures used in this research were computed from variables in the NELS data set. Whenever necessary, the original scale was recoded so that high values would reflect high levels of the construct. A conceptual description of these derived indicators is provided below.

### Background Variables

Number of grades completed outside the United States indicates how many grades (0–9), from kindergarten to eighth grade, the student attended outside the United States, according to parental reports. SES is a composite continuous variable available in the NELS data set. It was constructed primarily from base-year parental data (i.e., occupation, educational level, and family income) and is expressed in *z* score units, with higher values indicating higher SES.

### Language Proficiency Measures

Four L1 proficiency and four L2 proficiency measures were collected at Time 1 (Grade 8). For both their first (native) language

and their second language (English), students rated on a 4-point scale their own ability to understand, speak, read, and write. An evaluation of the psychometric properties of these measures is provided in a later section.

### Reading Achievement Test Scores

English reading achievement tests were administered three times (Grades 8, 10, and 12). Although several types of reading test scores can be found in the NELS data files, the most appropriate for longitudinal analyses are the estimated number correct scores generated by item response theory (IRT) procedures. Because their measurement is based on a common scale, these scores are comparable across waves and can be used to gauge achievement gains over time (see Ingels, Scott, Rock, Pollack, & Rasinski, 1994, for details).

### High School Achievement

Four observed variables, measured at Time 3 (Grade 12), were used to assess the relations among individual differences in English reading trajectories and high school completion, rigor of the academic educational program, and overall scholastic achievement.

Number of Carnegie units is a transcript-based indicator that captures, to some extent, the quality of the student's high school curriculum. It expresses the total number of Carnegie units completed by the student in the New Basic subject areas: math, science, English, social studies, computer science, and foreign languages.

Graduation status is a composite measure of high school degree attainment and drop-out history that indicates what type of high

school degree (if any) the student attained and whether the student's degree attainment history was marked by one or more drop-out episodes (0 = *no diploma or equivalent*; 1 = *GED or certificate, with a positive drop-out history*; 2 = *standard high school diploma, with a positive drop-out history*; 3 = *standard high school diploma, with a negative drop-out history*). This measure was based on both self-report and transcript data.

Grade 12 GPA is the student's average grade point average, computed from transcripts, across all math, science, English, and social studies courses taken during the 12th grade. Those academic areas were chosen because they are core subjects, and grades in those areas were available for most students. The restricted-use data set provides standardized grade codes that represent conversions of letter grades and percentages to a common metric. These scores were recoded so that higher values would reflect a higher GPA (1 = *F*, 13 = *A+*).

Class rank is another transcript-based variable that indicates the student's class rank during the last year of school. To account for differences in class size, I converted the original raw scores into percentile ranks.

### *Distal Outcomes*

Three observed measures, collected at Time 4 (i.e., 8 years after graduation from high school), provide an index of the student's long-term post-secondary and occupational attainment.

Postsecondary degree indicates the highest level of post-secondary education attained (0 = *no postsecondary education*; 1 = *some postsecondary education but no degree attained*; 2 = *attained an associate's degree*; 3 = *attained a bachelor's degree*; 4 = *attained a master's degree but not higher*; 5 = *attained a Ph.D. or professional degree*).

An occupational prestige variable was constructed from Time 4 questionnaire data. NELS provides occupational codes and titles for jobs held by participants. The job title list, as well as Appendix D from Nakao and Treas' (1994) occupational prestige study, were given to three undergraduate assistants who were asked to match each job title with the appropriate Nakao-Treas prestige score. I also completed this matching task. Interrater reliability was very high (intraclass correlation = .960). To calculate the final prestige scores, I averaged the four coders' ratings, except in a few cases of obvious coding error when a single aberrant rating was excluded.

Salary is a measure of annual earning rate, computed from two NELS variables: amount earned and pay period (hourly, weekly, biweekly, monthly, or annually).

### *General Analytic Strategy*

When longitudinal data are available, the analysis of change and the modeling of intraindividual and interindividual developmental trajectories are made possible by latent growth curve methods, which operate within the general framework of structural equation modeling (SEM). In this research, latent growth model fitting and estimation procedures were carried out with Mplus Version 4.1 (Muthén & Muthén, 2006). Before the results of these analyses are reported, some critical methodological issues need to be considered.

### *Complex Survey Sample Design*

Because of the multistage, stratified, cluster sample design of the NELS survey, it would be inappropriate to analyze the data as if they

originated from a simple random sample. The biasing effect of unequal probability of selection and nonresponse is one of the analytic challenges presented by this sampling scheme. Sample weighting is necessary to prevent inaccurate estimates of population parameters (Asparouhov, 2005; Stapleton, 2002). In the analyses reported here, the NELS nonresponse-adjusted weight "f4trscwt" was used to weight the cases to population totals. This weight applies to students who participated in the four waves of the study and for whom transcript data were available (Curtin et al., 2002).

Another analytic issue raised by complex multistage sampling designs concerns the multilevel nature of the data they generate. Surveys such as NELS, in which students are nested within schools and schools are nested within larger units (i.e., geographical regions), yield data that have a hierarchical structure. The analytic perils of ignoring the complex data structure have been repeatedly delineated (Hox, 2002; Julian, 2001; Muthén & Satorra, 1995). A measure of the impact that clustering and dependencies among observations have on the precision of variance estimation is provided by the design effect (DEFF). DEFF size is a function of both the intraclass correlation (ICC) and cluster size (Julian, 2001; Muthén & Satorra, 1995). Although in the present study the average cluster size was only 2.31, ICCs ranged from .09 to .28. Some of the resulting DEFFs were thus large enough that failure to account for the hierarchical structure of the data could have produced biased standard error estimates.

Two data analytic strategies are available in Mplus when the data to be modeled have a complex sample structure. The "type = complex" option does not provide estimates of between-level and within-level variance components, but it permits specification of stratum, cluster, and weight variables needed to generate standard errors and goodness-of-fit indices that take into account the nonindependence of observations associated with stratified cluster sampling designs. In a Monte Carlo simulation, Muthén and Satorra (1995) found that this analytic option is particularly robust to violations of nonnormality and is suitable for a variety of sampling designs and types of data (e.g., dichotomous variables). This solution to the complex design problem was preferred to the "two-level" alternative because the key issue examined here was the extent to which L1 proficiency, developed prior to eighth grade, predicts academic and vocational achievement in LEP students; the focus was not on school-level effects, which would require modeling within-school and between-schools variance components in two-level analyses. Moreover, when the type = complex analytic strategy is chosen, Mplus (Version 3.1 and later) allows the option of including a stratification variable, in addition to cluster and sampling weight information. In a series of simulation studies, Asparouhov (2004) demonstrated that failure to include stratum information in the analysis (even when cluster is specified) can markedly influence model rejection rates. Similar conclusions were reached more recently by Stapleton (2006), who conducted a simulation study in which five estimation approaches, in the presence of complex sample data, were compared under different analytic scenarios. She found that the estimation method used in the present research yielded the most robust parameter and standard error estimates under all analytic conditions.

### *Missing Data and Nonnormality*

Invariably, longitudinal research presents the problem of what to do with missing data. Reviews and empirical comparisons of methodological approaches for dealing with missing data (e.g., Enders &

Bandalos, 2001; Newman, 2003; Schafer & Graham, 2002) uniformly point to the same general conclusions. When data are missing completely at random (MCAR) or when data are missing at random (MAR), multiple imputation (MI) and maximum likelihood (ML) estimation procedures greatly outperform traditional approaches, such as pairwise deletion, listwise deletion, mean imputation, and hot deck procedures. Full information maximum likelihood (FIML), a particular ML algorithm implemented in many leading SEM software packages (including Mplus), has been found especially effective (Enders & Bandalos, 2001). Although the MCAR missingness assumption rarely holds in applied research (Kline, 2005), Schafer and Graham (2002) suggested that it is appropriate to proceed under the less restrictive and more realistic MAR assumption. As they conclude in their authoritative review, "ML and MI under the MAR assumption represent the practical state of the art" (p. 173). This was the approach used in the present study.

In addition to MAR data, multivariate normality is a key assumption of ML estimation. Mplus can handle departures from normality in the presence of missing data by computing robust standard errors with a sandwich estimator and applying a scaling correction to adjust the chi-square test statistic (Muthén & Muthén, 2006). This corrected chi-square is the Yuan–Bentler test statistic (Yuan & Bentler, 2000), an extension of the Satorra–Bentler scaled chi-square ( $\chi^2_{SB}$ ) to the case of missing data.<sup>3</sup> Bentler and his associates (Chou & Bentler, 1995; Gold, Bentler, & Kim, 2003; Savalei & Bentler, 2005) found that when the data are incomplete and nonnormal and when the mechanism of missingness is MCAR or MAR, ML estimation with the Yuan–Bentler correction provides accurate parameter estimates, standard errors, and test statistics.

### *Assessment of Model Fit*

The results of covariance structure analyses with large samples cannot be properly evaluated by means of the  $\chi^2$  goodness-of-fit statistic alone. Given a sufficiently large sample size, any model can be rejected on the basis of the  $\chi^2$  test, no matter how small the discrepancy between the observed and the estimated covariance matrices (Kline, 2005). Although many alternative fit indices are now available, and their relative merits continue to be debated (e.g., Fan & Sivo, 2005; Marsh, Hau, & Wen, 2004), the recommendations issued by Hu and Bentler (1998, 1999) have gained wide acceptance. Consistent with those recommendations, the indices used in the present research include the comparative fit index (CFI; Bentler, 1990), the root-mean-square error of approximation (RMSEA; Steiger & Lind, 1980), and the standardized root-mean-square residual (SRMR; Bentler, 1995). With respect to cutoff values for these indices, Hu and Bentler (1999) recommend that CFI be close to .95, RMSEA be close to .06, and SRMR be close to .08.

### *Results*

The two language proficiency constructs are at the core of the theoretical model tested in this study. Thus, before reporting the results of the latent growth analyses, it is important to examine the psychometric characteristics of those self-report measures. Most of the other variables used in this study were derived either from student transcripts or from the cognitive test battery that was administered three times over a 4-year period. The reliability and validity of those instruments have been fully evaluated and are

clearly established (Rock & Pollack, 1991, 1995). Technical reports by the NCES (Kaufman & Rasinski, 1991; McLaughlin & Cohen, 1997) have in many cases also reached favorable conclusions about the psychometric properties of the student questionnaire data. The findings of those evaluations, however, tend to be domain specific, wave specific, and source specific and do not allow general conclusions about the quality of the self-report data, particularly of the language proficiency measures.

A substantial linguistic literature points to the criterion-related validity of language proficiency self-assessments. In a review of 21 studies, Blanche and Merino (1989) found that typical correlations between self-ratings and objective indicators of L2 proficiency range between .50 and .60. The results of a more recent meta-analysis by Ross (1998) were consistent with Blanche and Merino's conclusions and indicated that for each of the four language skills (i.e., understanding, speaking, reading, and writing), validity coefficients range from .51 to .65. Very similar and even higher validity coefficients have been reported for self-assessment of L1 proficiency (Delgado, Guerrero, Goggin, & Ellis, 1999; Shameem, 1998). In a study by Hakuta and D'Andrea (1992) that is particularly relevant to the present research, 308 high school students of Hispanic origin were asked to provide ratings of both their Spanish proficiency and their English proficiency, which were then compared with standardized proficiency measures. The validity coefficients were .61 for L1 and .46 for L2. Although these findings offer general support for the psychometric adequacy of language proficiency self-assessments, the reliability and validity of the NELS-based language proficiency measures used in this research need to be directly evaluated.

### *Psychometric Properties of NELS:88/2000 Language Proficiency Measures*

#### *Reliability*

Students who indicated that a language other than English was spoken at home were asked to rate their ability to understand, speak, read, and write that language as well as English. Self-ratings of L1 proficiency were taken at base year (Time 1) and again 2 years later at the first follow-up (Time 2). English proficiency ratings were taken three times, at intervals of 2 years. Excellent reliability and stability were found for both L1 and L2 proficiency measures at all assessment waves. Internal consistency (Cronbach's alpha) for L1 proficiency was .86 at both Time 1 and Time 2. Alpha coefficients for L2 proficiency were .91, .93, and .90 at Time 1, Time 2, and Time 3, respectively. For each of the four language skills that make up the L1 proficiency construct, the correlations between Time 1 and Time 2 measures ranged from .55 to .70 ( $M = .63$ ). For L2 skills, correlations between adjacent waves yielded stability coefficients ranging from .35 to .56 ( $M = .50$ ), whereas correlations between Time 1 and Time 3 measures ranged from .26 to .54 ( $M = .44$ ). It is plausible that differences in self-ratings over time reflect not just measurement error but also individual differences in language proficiency trajectories, which would then attenuate the correlations, especially between nonadjacent assessment occasions.

<sup>3</sup> Unless otherwise noted, all chi-squares reported in this article are computed with the Yuan–Bentler scaling correction.

Table 1  
*Multitrait–Multimethod Correlation Matrix for Two Assessment Methods and Two Traits Measured at Time 1 and at Time 2*

Method/measure	Self-report				Objective assessment			
	1	2	3	4	5	6	7	8
Self-report								
1. L2 proficiency at T1	—							
2. Non-English grades at T1	-.051	—						
3. L2 proficiency at T2	.542	.029	—					
4. Non-English grades at T2	-.038	.470	-.064	—				
Objective assessment								
5. IRT reading scores at T1	.297	.328	.324	.247	—			
6. Non-English GPA at T1	.085	.379	.134	.499	.413	—		
7. IRT reading scores at T2	.261	.307	.315	.273	.773	.451	—	
8. Non-English GPA at T2	-.026	.379	.082	.578	.311	.611	.392	—

Note. Because of the large sample size ( $N = 1,804$ ), correlations as small as .047 are significant at  $p < .05$ . T1 = Time 1 data collection; T2 = Time 2 data collection; IRT = item response theory, GPA = grade point average.

### Construct Validity: A Multitrait–Multimethod Model

A second important issue concerns the construct validity of the L1 and L2 proficiency measures that are based on self-report and are therefore vulnerable to selective distortion by self-presentational biases and other response sets. Students' self-rated proficiency measures reflect three sources of variance: (a) trait variance, which is systematic variance, independent of assessment method, that represents true differences in ability level; (b) method variance, which is systematic variance specifically associated with the use of self-report (e.g., the tendency to be influenced by social desirability concerns); and (c) error variance, which includes both residual systematic variance and measurement error (e.g., misreading or misunderstanding a question). In order to determine whether self-ratings of language proficiency reflect true variations in ability, one must disentangle the contributions of trait effects, method effects, and error effects. Moreover, if L1 or L2 proficiency were found to predict favorable academic and occupational outcomes, it would be important to rule out the possibility that those associations were simply the byproduct of a general intellectual ability factor.

The multitrait–multimethod (MTMM) approach pioneered by Campbell and Fiske (1959) can be used to decompose the total variance and to assess the convergent and discriminant validity of psychological measures. This design requires that two or more traits be assessed with two or more methods. Regrettably, the NELS data set provides no measure of L1 proficiency other than self-report. More objective indices of proficiency, against which one could validate students' self-ratings, however, are available for L2. Table 1 shows a MTMM matrix that includes two methods (self-report and objective measurement) and two traits (L2 proficiency and achievement in academic subjects other than English) assessed at two points in time (Grades 8 and 10).<sup>4</sup> The objective indicators of the two traits are based on transcripts and on standardized test scores. The non-English achievement indicators, included to test the discriminant validity of the L2 proficiency measure, represent self-reported and transcript-based grades in math, science, and social studies courses.

Longitudinal confirmatory factor analysis (CFA) of the MTMM matrix was used to evaluate the construct validity and temporal stability of self-reported L2 proficiency. The CFA model (see

Figure 2) includes two trait factors across two waves, two method factors, and eight observed variables. For each wave, one self-report variable and one objective assessment variable were specified to load on each trait.<sup>5</sup> The manifest variables that at each wave were hypothesized to load on the L2 proficiency trait factor were the IRT-estimated reading scores and a self-reported proficiency measure computed by averaging students' self-rated ability to understand, speak, read, and write English.<sup>6</sup> The two indicators that were specified to load at each wave on the Non-English Achievement trait factor were (a) non-English grades, which were computed by averaging students' self-reported grades in math, science, and social studies, and (b) non-English GPA, which was

<sup>4</sup> Although L2 proficiency ratings are available also at Time 3 (second follow-up questionnaire), a self-report measure of grades in various academic subjects was not included at that time. Thus, only the first two waves of data could be used to test the model.

<sup>5</sup> There is considerable debate on the advantages and disadvantages of various CFA parameterizations of MTMM matrices (see Brown, 2006, for a recent review). The correlated trait-correlated method (CT-CM) approach was used in the present research for the theoretical and substantive reasons articulated by Conway, Lievens, Scullen, and Lance (2004) and by Lance, Noble, and Scullen (2002). This parameterization, however, is notorious for returning ill-defined solutions (Kenny & Kashy, 1992). The problem is often remedied with the use of large samples (e.g., Lance et al., 2002). Since the data to be modeled no longer required participation in all waves of the study, the CFA–MTMM model was tested on 1,804 participants who met the inclusion criteria described in Figure 1, participated in the first and second follow-ups, and had transcript information. The data were weighted with "f2trp1wt," the appropriate NELS weight in panel analyses in which survey and cognitive test data are combined with transcript data.

<sup>6</sup> In an alternative model, the mean of the four language skills was replaced with only the reading self-rated skill that was specified to load, together with the IRT reading measure, on a L2 reading proficiency trait factor. Estimation of this model produced a "not positive definite matrix" solution, probably as a result of a very high correlation between Time 1 and Time 2 reading proficiency factors ( $r = .993$ ). The fit of this model, the parameter estimates, and the standard errors, however, were substantively interchangeable with those of the model shown in Figure 2.

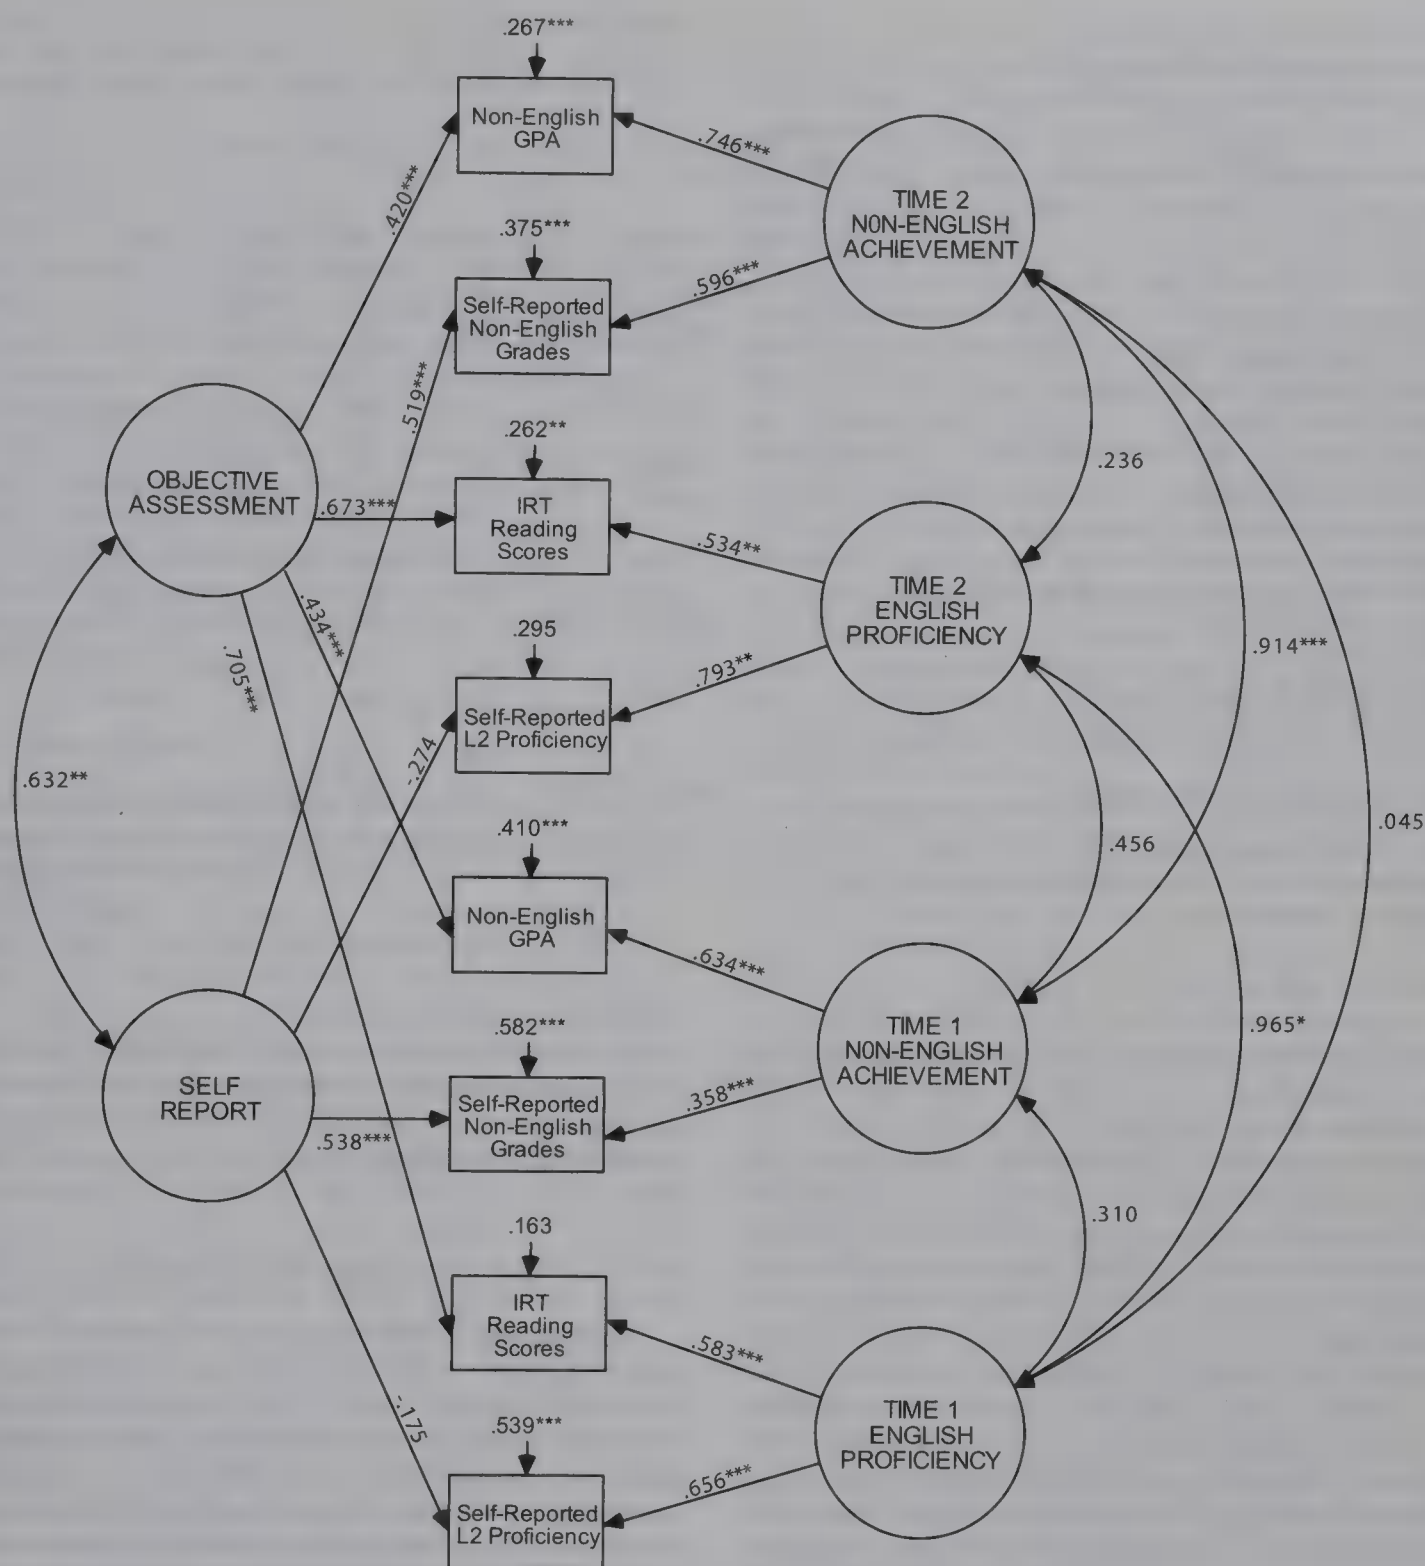

Figure 2. Multitrait-multimethod confirmatory factor analysis model of two correlated traits and two correlated methods across two measurement waves. Completely standardized robust maximum likelihood parameter estimates. The residual variance components (error variances) indicate the amount of unexplained variance. Thus, for each observed variable,  $R^2 = (1 - \text{error variance})$ . GPA = grade point average; IRT = item response theory; L2 = English. \* $p < .05$ . \*\* $p < .01$ . \*\*\* $p < .001$ .

the transcript-based average of students' GPA in math, science, and social studies.<sup>7</sup>

The fit of the CFA-MTMM model displayed in Figure 2 was excellent,  $\chi^2(5, N = 1,804) = 10.236$ , CFI = .994, RMSEA = .024, SRMR = .015 (see Model 1 in Table 2, which summarizes the fit of all the models tested in the present investigation). For both waves, all measures loaded significantly ( $p < .001$ ) on their respective trait factors, even after shared method variance was

controlled. This indicated good levels of convergent validity. Discriminant validity of the measures was demonstrated by the non-

<sup>7</sup> The non-English GPA variable for Time 2 is an average of standardized course grades obtained in 10th grade. The NELS transcript file, however, includes eighth-grade GPA for only a handful of students; thus ninth-grade courses were used to derive the Time 1 non-English GPA variable.

\* $p < .05$ .

significant correlations between different trait factors, both within and across measurement occasions. At the same time, the very high correlations for the same trait factor across time indicated excellent temporal stability of the constructs. Table 1 shows that heterotrait-monomethod correlations were generally higher in the objective assessment block than in the self-report block, indicating greater shared method variance for the objective measures than for the self-report measures. The squared factor loadings of each measure on its respective trait and method factors made it possible to partition the total variance into trait, method, and error components. Again, large method effects were evident for the objective measures, all of which loaded significantly ( $p < .001$ ) on their method factor. Method effects were smaller but also significant for the self-report non-English grade measures and were nonsignificant for the self-report L2 proficiency indicators. Noteworthy was the large amount of trait variance relative to method variance for both waves, particularly for the self-report measures. Overall, averaging variance components across all measures and across the two measurement occasions indicated that 39.1% of the variance in the measures was explained by trait variance, 24.7% was explained by method variance, and the remaining 36.2% was due to error.

Taken together, these findings are reassuring with regard to the reliability, stability, and construct validity of the L2 proficiency self-ratings. The L2 proficiency measure loaded strongly on the same trait factor on which IRT-estimated English reading scores loaded significantly. In addition, the nonsignificant correlations between L2 proficiency and academic achievement in non-English subjects suggest that L2 skills were not byproducts of a general cognitive ability factor. It seems reasonable to extend to the L1 proficiency measure the favorable conclusions reached about the

psychometric characteristics of the L2 proficiency variable, particularly considering that criterion-related validity coefficients have repeatedly been found to be higher for L1 than for L2 self-assessment (e.g., Delgado et al., 1999; Hakuta & D'Andrea, 1992).

Latent Growth Curve Analyses

The key hypothesis under examination in this study was that L1 proficiency would predict the development of L2 reading skills in LEP students, and this, in turn, would be associated with successful academic and occupational outcomes. IRT English reading scores from three points in time—8th, 10th, and 12th grades—were available. Thus, the first step was to establish whether this sample of LEP students showed evidence of growth in reading scores and whether there were substantial individual differences in growth. Furthermore, prior to evaluating the structural component of the model, the validity of the measurement model needed to be assessed. Assuming confirmation that the manifest indicators adequately measured their respective latent factors and assuming a reasonable level of interindividual variation in initial reading scores and rate of change, one could then evaluate the hypothesized relations among latent constructs.

The longitudinal structure of the data makes these research questions ideally suited for latent growth modeling (LGM) analyses, which become possible when at least three measurement occasions are available for the repeated measure variable. Although multistep modeling strategies have been the object of some controversy (e.g., see *Structural Equation Modeling* [2002], 7, [1], the analytic approach adopted in the present research followed

Tomarken and Waller's (2003) sensible recommendation to parse complex SEM models into smaller and theoretically meaningful components.

### *Descriptive Statistics*

All 899 LEP students were included in the analyses. Means, standard deviations, and intercorrelations for the 20 observed variables are reported in Table 3. Although some variables were not normally distributed, transformations were not applied because, as discussed earlier, the complex sample analytic option in Mplus automatically invokes the "MLR (maximum likelihood robust) estimator," which provides FIML parameter estimates and standard errors that are robust against violations of distributional assumptions (Muthén & Muthén, 2006). The only exception was the salary variable. Its very large variance, skew, and kurtosis values caused convergence problems during model fitting. Dividing salary values by 10,000 and applying a cubic root transformation remedied the problem.

### *Single Group Analyses*

The analytic steps outlined above were first applied to the full LEP sample ( $N = 899$ ). The issue of group differences will be considered in a later section.

*The growth model.* Figure 3 shows a simple two-factor unconditional (i.e., no covariates specified) latent growth model in which reading scores at three points in time are indicators of two latent growth factors, reading intercept and reading slope. The first factor represents the initial level of English reading achievement (i.e., eighth-grade IRT reading scores), and the second factor represents the slope of individual trajectories in the development of English reading ability over time. For any given student, the initial reading value remains the same across the three time points; therefore, as is customary in LGM, the three intercept loadings were fixed to 1. The assumption of linear change in reading scores across time was modeled by fixing the three slope loadings to 0, 1, and 2 for the first, second, and third measurement occasion, respectively.

Estimation of the model displayed in Figure 3 yielded a very good fit,  $\chi^2(1) = 4.290$ , CFI = .997, RMSEA = .061, SRMR = .015 (Model 2, Table 2). Although there was a tendency for initial L2 reading scores to be positively associated with rate of reading improvement ( $r = .214$ ), the estimated covariance between intercept and slope factors was not significant. On the other hand, the means of both growth factors were significantly different from zero. The mean reading score at the first measurement occasion (i.e., the initial value) was 21.01,  $p < .001$ , and the mean rate of improvement over time was 2.57 units for each measurement occasion,  $p = .01$ . In addition, the variances of both growth factors were significantly different from zero ( $p < .001$  and  $p < .01$  for the intercept and slope, respectively). The latter finding indicated the presence of significant interindividual variation in both initial reading level and rate of growth from Grade 8 to Grade 12, and it obviously raised the question of what might account for that variance, an issue that will be fully elaborated in a subsequent sentence.

*The measurement model.* A four-factor CFA model that included all the latent constructs (except for the two growth factors) to be incorporated into the full structural model, together with their

respective indicators, is shown in Figure 4. Time 1 self-ratings of the ability to speak and understand either English or one's native language reflect oracy skills that are likely to share common omitted causes. Thus, for the two language proficiency constructs, the residuals of oracy indicators (speaking and understanding) were allowed to correlate not only because of their large modification indices, but also because such model modification was justified on theoretical grounds (e.g., Delgado et al., 1999). Because of convergence difficulties, however, the uniquenesses of the literacy measures (reading and writing) were not allowed to correlate. The fit of the measurement model diagrammed in Figure 4 was very good,  $\chi^2(82) = 190.213$ , CFI = .961, RMSEA = .038, SRMR = .043 (Model 3, Table 2). Thus, the hypothesized relations of manifest indicators to their underlying factors were confirmed. All factor loadings were significant at  $p < .001$  or better and in the expected direction. For both L1 and L2, reading and writing self-ratings had the highest loadings (all  $> .90$ ) on the proficiency factors, which indicated that literacy components played a very prominent role in the definition of language proficiency. For both L1 and L2 literacy indicators, the proportion of variance explained by their respective latent factor ranged from .827 to .908 (see Figure 4).

Assessment of the measurement model provided good evidence for both convergent and discriminant validity. All of the observed measures of the same construct loaded significantly on that construct, and the low intercorrelations among factors (except for the expected covariation between the two achievement factors) indicated that those factors represent different constructs. Having established the validity of the model's factorial structure, it was then appropriate to examine the structural relations among constructs.

*The full conditional LGM model.* The key assumptions of bilingual education theory served as the theoretical foundation for specification of the full latent growth model presented in Figure 5, which includes both measurement and structural components. Self-reported L1 and L2 proficiency were hypothesized to explain variation in reading growth. L1 proficiency was expected to predict the initial level (L2 reading intercept) and, more important, the developmental trajectories of students' L2 reading achievement (L2 reading slope). L2 proficiency was also hypothesized to have a direct relation with the latent growth factors that, in turn, were expected to predict both high school achievement and more distal educational and occupational sequelae. Direct effects of L1 and L2 proficiency on high school and post-high school achievement were not specified because the language proficiency measures were hypothesized to predict academic and occupational attainment through the development of English reading skills. SES and number of grades completed outside the United States prior to the eighth grade are time-invariant covariates that were added to the model because they might predict individual differences in L1 and L2 proficiency, reading growth factors, and high school achievement. The full LGM model fit the sample data quite well,  $\chi^2(150) = 343.074$ , CFI = .952, RMSEA = .038, SRMR = .050 (Model 4, Table 2). Completely standardized estimates, together with their significance levels, are included in Figure 5.

Self-reported L1 proficiency was significantly predicted by number of grades completed outside the United States, as was L2 proficiency, but the latter path coefficient was negative. These

L2 = English; IRT = item response theory. \* $p < .05$ . \*\* $p < .01$ . \*\*\* $p < .001$ .

findings were not unexpected; the longer students had been schooled abroad, the greater their native language proficiency and the lower their English proficiency (or, at least, the lower their confidence in their English proficiency). Paths from SES to both language proficiency measures were also significant, but in the opposite direction (i.e., negative for L1 proficiency and positive for L2 proficiency). From a theoretical perspective, the most interesting findings relate to the test of the bilingual education assumptions. As expected, L2 proficiency was a significant predictor of initial L2 reading level, but it did not predict improvement in reading over time. On the other hand, L1 proficiency significantly predicted both initial English reading status and rate of English reading growth from Grade 8 to Grade 12, even after the influence of being schooled abroad and SES was controlled. Figure 5 also shows significant path coefficients from the two latent growth factors to high school achievement, from high school achievement to post-high school achievement and from both growth factors to post-high school achievement.<sup>8</sup> Overall, the variables in the model explained 12.9%, 3.9%, 30.7%, and 55.9% of the variance in initial English reading scores, English reading rate of improvement, high school achievement, and post-high school achievement, respectively (see Figure 5).

### Multigroup Analyses

The operating assumption, up to this point, has been that the LEP sample examined in this study was a homogeneous group and that the model parameters (factorial structure, growth processes, mean and covariance structures) applied equally to all members of

this group. In actuality, this LEP sample was very diverse with respect to ethnic, linguistic, and cultural characteristics. The two largest ethnic groups were Hispanics ( $n = 451$ ) and Asian/Pacific Islanders ( $n = 254$ ).<sup>9</sup> The remaining 194 LEP students included relatively small groups of non-Hispanic Whites, non-Hispanic Blacks, and American Indians/Alaskan Natives. The obvious question was whether the model captured in Figure 5, which fit the full sample data well, would be invariant across these ethnic groups. Sample size requirements for SEM analyses, as well as the desirability of relative group homogeneity, made it advisable to test for equivalence of parameter estimates only across the two largest LEP groups, Asians and Hispanics.

The process of evaluating multigroup invariance of measurement and structural model components typically involves testing a series of hierarchically nested and increasingly restrictive models, in which cross-group equality constraints are progressively imposed on key parameters. At each step, the fit of the more restricted model is compared against the fit of the less restricted model, and a nonsignificant chi-square difference (likelihood ratio) test is usually taken as evidence of invariance.<sup>10</sup> Because the chi-square difference test ( $\Delta_{\chi^2}$ ) is also sensitive to sample size, Cheung and Rensvold (2002) have argued that changes in goodness-of-fit indices should be used to assess differences in fit between pairs of nested models. The results of their simulation study indicated that change in CFI ( $\Delta_{CFI}$ ) is a robust index of invariance, and they proposed a  $\Delta_{CFI}$  cutoff value of .01 (i.e., a drop in CFI in the more restricted model, compared with the baseline model, equal to or smaller than .01 should lead to the conclusion that the invariance hypothesis cannot be rejected). Thus, in the present study acceptance of the multigroup invariance hypothesis required both a nonsignificant  $\Delta_{\chi^2}$  and a  $\Delta_{CFI}$  equal to or less than .01.

*Separate group analyses.* The final conditional LGM model was first estimated for each group separately. The fit of the model for the Hispanic sample was quite satisfactory,  $\chi^2(150, N = 451) = 355.490$ , CFI = .934, RMSEA = .055, SRMR = .064

<sup>8</sup> In an effort to identify other control variables that might predict L1 or L2 proficiency or the two growth factors, a model with five additional covariates was specified and estimated. These covariates included home variables (i.e., parental educational aspirations) and school-based variables either available in the NELs database (i.e., percentage of students receiving free lunch, percentage of minority students) or computed from original NELs variables (i.e., teachers' attitudes and morale, student behavior problems). The overall pattern of results for this expanded model was remarkably similar to that of the model displayed in Figure 5, but the more complex model had a poorer fit, and none of the additional variables was a significant predictor of rate of improvement in English reading; thus, those additional five covariates were not included in the final conditional model.

<sup>9</sup> Henceforth, I will refer to this group as *Asians* not only for reasons of simplicity but also because only 7 students in this group identified themselves as Pacific Islanders.

<sup>10</sup> The standard chi-square difference test cannot be used to compare the fit of nested models when the Satorra-Bentler or the Yuan-Bentler scaled test statistic is used to evaluate the fit of those models because such difference is not distributed as  $\chi^2$  (Satorra & Bentler, 2001). Step-by-step instructions for computing the correct  $\Delta_{\chi^2}$  in these cases are provided by Mplus at <http://www.statmodel.com/chidiff.html>. All chi-square difference tests reported in this article were computed following those guidelines.

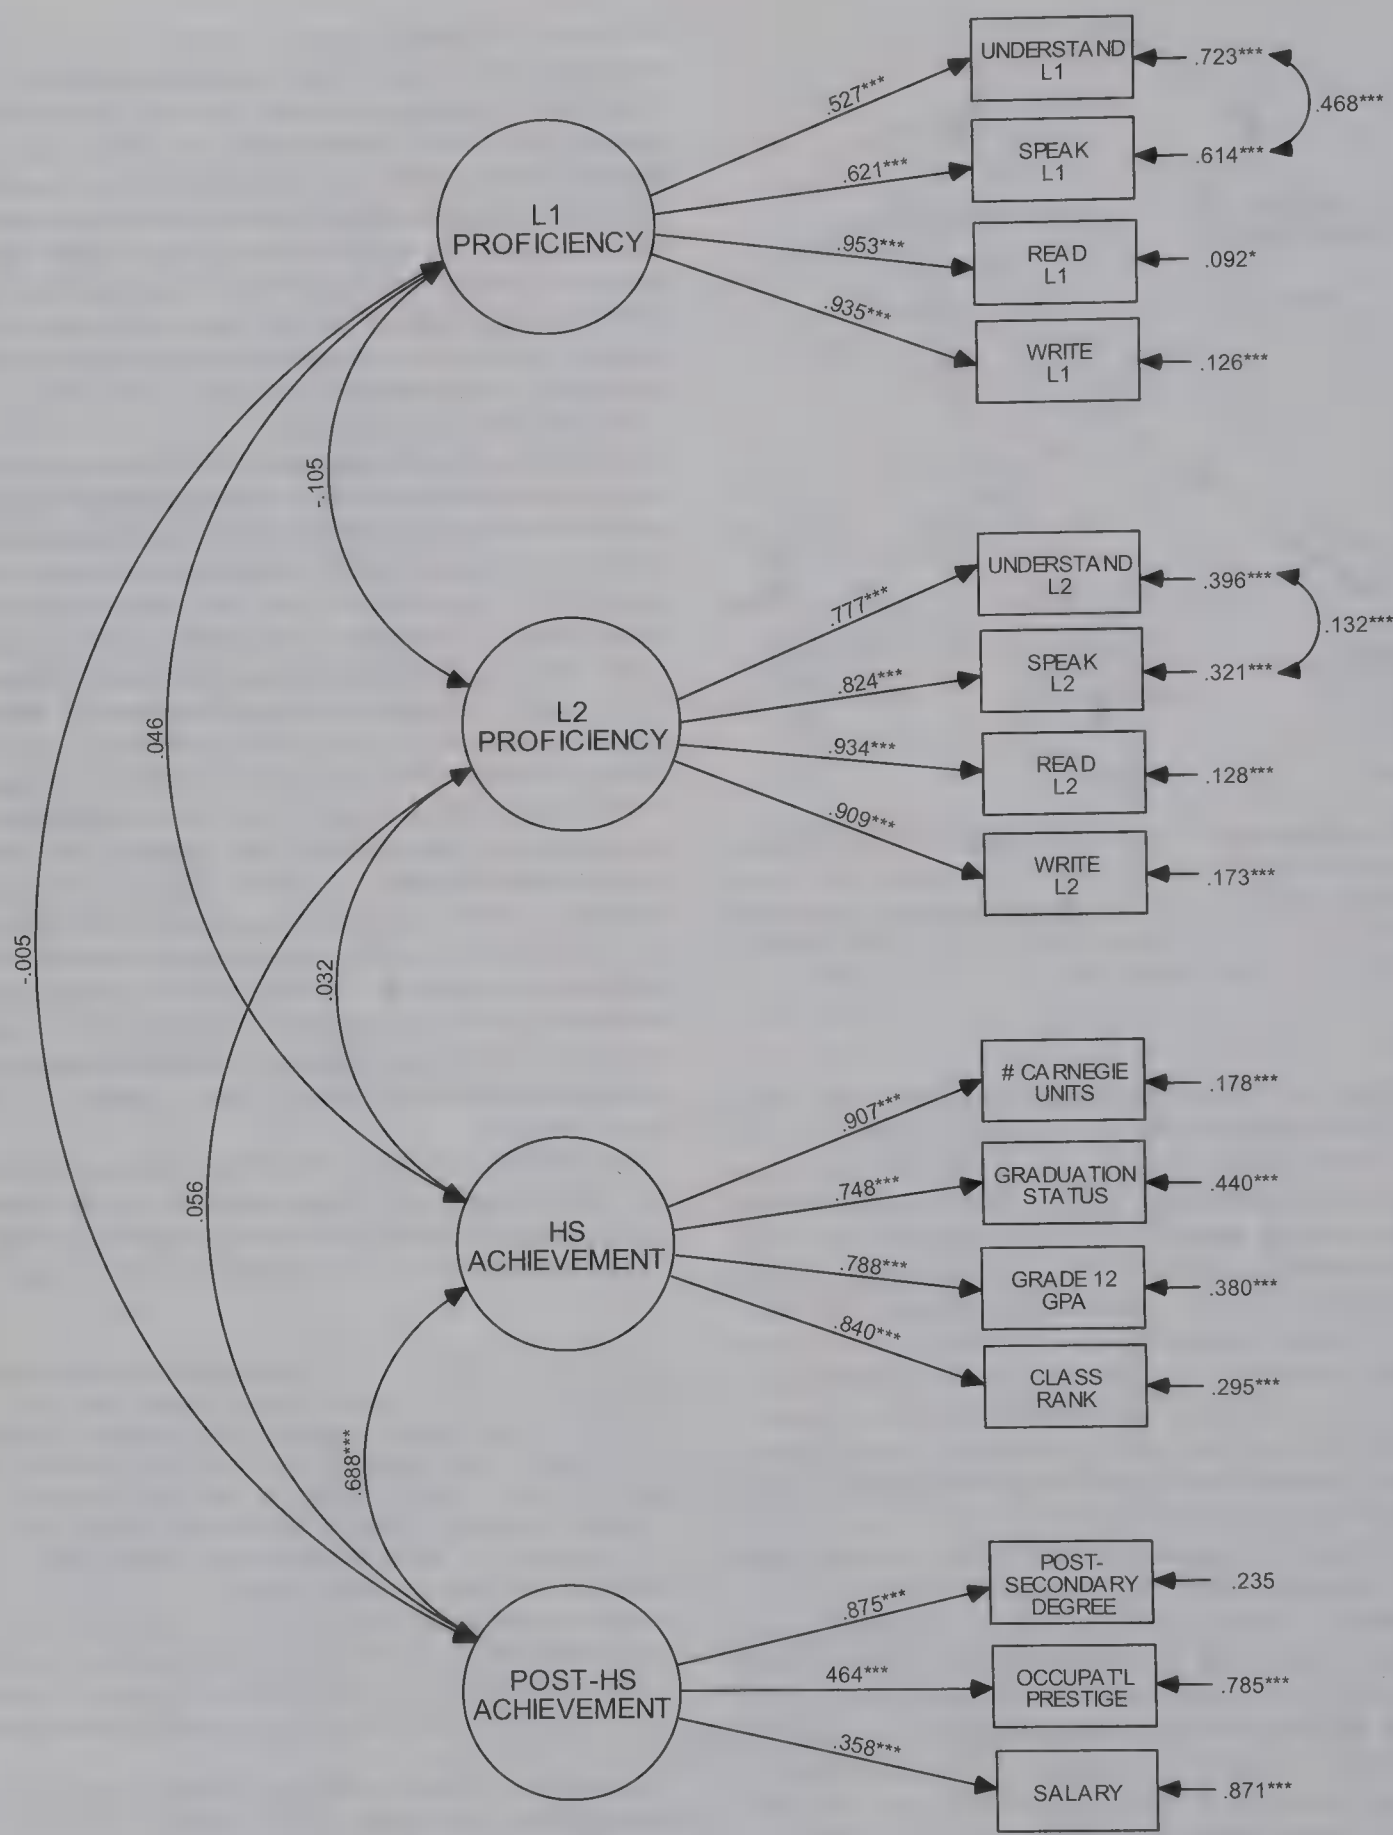

Figure 4. Confirmatory factor analysis model. Completely standardized robust maximum likelihood parameter estimates. The residual variance components (error variances) indicate the amount of unexplained variance. Thus, for each observed variable,  $R^2 = (1 - \text{error variance})$ . L1 = native language; L2 = English; HS = high school; GPA = grade point average. \*  $p < .05$ . \*\*  $p < .01$ . \*\*\*  $p < .001$ .

(Model 5, Table 2). Figure 6 shows the completely standardized estimates and their significance levels for the Hispanic students.

The general pattern of findings for this group was very consistent with the results of single group analyses. Again, both L1 and L2 proficiency significantly predicted initial L2 reading achievement scores ( $\beta = .274$ ,  $p < .001$ , and  $\beta = .185$ ,  $p < .05$ , respectively). L1 proficiency but not L2 proficiency, however, was significantly related to gains in English reading achievement over time ( $\beta = .257$ ,  $p < .005$ ), even after the effect of being schooled abroad and of SES was controlled. In fact, L1 proficiency remained the only significant predictor of English reading slope in an expanded model in which five additional family and school variables were added as covariates. In the Hispanic sample, the variables in the model explained 24.1%, 7.4%, 29.4%, and 46.3% of the variance in initial English reading level, English reading rate of growth, high school achievement, and post-high school achievement, respectively (see Figure 6).

When the same model was estimated for the Asian group, instead, there was evidence of very poor fit to the data,  $\chi^2(150, N = 254) = 641.974$ ,  $CFI = .778$ ,  $RMSEA = .114$ ,  $SRMR = .098$  (Model 8, Table 2). Particularly striking in this group was the complete absence of L1 proficiency effects on both the English reading intercept ( $\beta = -.027$ , *ns*) and the English reading slope ( $\beta = .014$ , *ns*). In addition, L2 proficiency was found to predict reading intercept ( $\beta = .244$ ,  $p < .05$ ) but not reading slope ( $\beta = .035$ , *ns*). In fact, none of the variables in the model (and none of the five additional covariates included in the expanded model) predicted English reading slope.

The separate group analyses strongly suggested that native language proficiency might play a very different role in the two groups. In the Hispanic sample, L1 proficiency was a significant predictor of both initial L2 reading level and gains in reading achievement over time. In the Asian sample, however, neither of those paths was significant. A fundamental assumption of the bilingual education approach is that L1 proficiency is critically important in the academic development of LEP students. The findings of the separate group analyses indicated that the maintenance and further development of native language skills might not serve the needs of different ethnic groups equally well. I conducted a more formal evaluation of this hypothesis by estimating separately for the two groups a model in which the key bilingual education components were missing. In Figure 6, the bilingual education assumption is modeled by the paths from L1 proficiency to the growth factors. Thus, the effect of removing those paths on model fit would provide a measure of the validity of that assumption. The two paths were deleted by fixing them to zero, and the modified model was then estimated separately for the Hispanic and Asian samples. Since this model was nested within the full LGM model displayed in Figure 5, the  $\Delta\chi^2$  and the  $\Delta CFI$  can again be used to assess the impact of model modification on fit. In the Hispanic sample, respecification of the model was associated with a significant reduction in fit,  $\Delta\chi^2(2, N = 451) = 79.052$ ,  $p < .001$ ,  $\Delta CFI = .011$ , (Model 6, Table 2). In the Asian group, on the other hand, the chi-square value of the nested model was actually lower than that of the baseline model. This produced a negative  $\Delta\chi^2$  value, which is an improper solution (Model 9, Table 2) that might be associated with either a small sample size or model misspecification (Satorra & Bentler, 2001). It is interesting that eliminating the paths from L2 proficiency to the two growth factors did not

change the fit of the model in either group,  $\Delta\chi^2(2, N = 254) = 5.218$ , *ns*,  $\Delta CFI = .000$ , for the Asian sample (Model 10, Table 2), and  $\Delta\chi^2(2, N = 451) = 6.248$ ,  $p = .044$ ,  $\Delta CFI = .002$ , for the Hispanic sample (Model 7, Table 2). Although the Hispanic group's  $\Delta\chi^2$  barely reached statistical significance, the  $\Delta CFI$  index suggests that differences between the two models are effectively negligible. The noninvariance of the full LGM model across the two ethnic groups called for a systematic evaluation aimed at identifying the nonequivalent parameters.

*Growth invariance.* The simple two-factor latent growth model presented in Figure 3 was estimated simultaneously for the two groups (Model 11, Table 2), and the fit of this unrestricted model was used as a baseline against which to assess the fit of more restricted models. The fit of this model was excellent,  $\chi^2(2, N = 705) = 2.632$ ,  $CFI = .998$ ,  $RMSEA = .030$ ,  $SRMR = .016$ . This confirmed that for both groups, the same functional form of change (i.e., a linear growth trajectory) described well the pattern of intraindividual progress in reading that occurred between Time 1 and Time 3. Increasingly more restrictive nested models were then specified and fitted to the data in order to assess the invariance of specific growth parameters. As shown in Table 2, in each case the null hypothesis of equivalence could not be rejected. When the means of the growth factors were constrained equally across the two groups (Model 12, Table 2), there was no decrement in fit relative to Model 11,  $\Delta\chi^2(2, N = 705) = 4.018$ , *ns*,  $\Delta CFI = .008$ . This implies the absence of significant group differences in initial reading levels and in rate of reading growth across time. In the next model (Model 13, Table 2), equality constraints were imposed on the variances and covariances of the growth factors while the constraints on the means were maintained. Again, there was no significant drop in fit relative to Model 12,  $\Delta\chi^2(3, N = 705) = 3.529$ , *ns*,  $\Delta CFI = .002$ . These findings support the conclusion that individual differences in initial reading scores and in the rate of reading change were essentially the same in the two groups, and there were no group differences in the relation between the two growth factors.

*Measurement invariance.* Inspection of the model estimation output suggested that a possible source of group noninvariance might be found in the measurement part of the model. Thus, the four-factor CFA model (see Figure 4) was estimated simultaneously for the two groups (Model 14, Table 2), with no equality constraints imposed on the parameters, in order to determine whether the factor structure captured in the measurement model was invariant across those groups. The poor fit of this model,  $\chi^2(164, N = 705) = 580.206$ ,  $CFI = .889$ ,  $RMSEA = .085$ ,  $SRMR = .070$ , indicated inadequate cross-cultural configural invariance. The same factor structure did not hold for Asian and Hispanic students, which means that the underlying constructs were conceptualized in different ways by the two groups. In other words, the same set of observed indicators did not reflect the same underlying constructs in the two cultural groups. Failure to demonstrate configural invariance renders all subsequent group comparisons uninterpretable and meaningless (Ployhart & Oswald, 2004; Vandenberg, 2002; Vandenberg & Lance, 2000).

In a measurement model that includes more than one factor, it is difficult to determine the source(s) of configural nonequivalence. Rensvold (personal communication, cited in Vandenberg, 2002) indicated that constructs that fail the configural invariance test could be identified by evaluating them one at a time (see Cole,

Figure 6. Full latent growth conditional model (Hispanic group). Completely standardized robust maximum likelihood parameter estimates. The residual variance components (error variances) indicate the amount of unexplained variance. Thus, for each observed and latent variable,  $R^2 = (1 - \text{error variance})$ . SES = socioeconomic status; L1 = native language; L2 = English; IRT = item response theory; HS = high school; GPA = grade point average \*  $p < .05$ . \*\*  $p < .01$ . \*\*\*  $p < .001$ .

Bedeian, & Field, 2006 for a recent example). When this strategy was applied to the measurement model in the present research, clear evidence of noninvariance was found only for the L1 proficiency construct. Rensvold, however, also pointed out that a serious limitation of this approach is that constructs may hold different meanings across groups when they are tested alone compared with when they are embedded instead in a "conceptual neighborhood" (as cited in Vandenberg, 2002, p. 147) with other constructs.

### Discussion

Latent growth curve modeling procedures were used to test some key theoretical assumptions of bilingual education. In particular, the central question examined was whether proficiency in one's native language would predict the development of English reading skills, the sine qua non for satisfactory academic achievement and positive long-term outcomes. The hypothesized relations among those constructs were incorporated into the latent growth model diagrammed in Figure 5, which included three critical paths: L1 proficiency  $\rightarrow$  English reading growth  $\rightarrow$  high school achievement  $\rightarrow$  post-high school accomplishments. The results of model estimation procedures showed a good fit to the full LEP sample and to the Hispanic subsample data. On the other hand, a substantial discrepancy was found between the observed and the model-implied covariance matrices in the Asian subsample. There was evidence that measures of key constructs did not function equivalently in the two cultural groups. Thus, following an examination of the Hispanic subsample findings, which are consistent with the basic hypotheses tested in this study, I will discuss possible reasons for group noninvariance.

### Hispanic Sample

Although over 460 languages are spoken by LEP students, Spanish is the native language for more than 79% of them (Kindler, 2002). Improving educational outcomes for the large and rapidly growing Hispanic LEP population is a national priority and remains a challenge. The results of the present study suggest that encouraging the maintenance and development of native language skills might facilitate the acquisition of English literacy, which in turn predicts positive academic and postsecondary outcomes in this language minority group.

The central finding of the Hispanic sample analyses was that self-reported L1 proficiency predicted significantly both initial values of L2 reading achievement and rate of improvement in L2 reading across 4 school years. By contrast, self-reported L2 proficiency predicted starting values but not reading trajectories. In fact, L1 proficiency turned out to be the only significant predictor of rate of improvement in English reading. This path was significant even after controlling for the contribution of the two background variables and of L2 proficiency. Despite direct negative paths from number of grades completed abroad to both self-reported L2 proficiency and English reading intercept, number of grades in non-U.S. schools positively predicted both English reading intercept and English reading slope through its association with L1 proficiency, which appeared to operate as a suppressor variable in this set of relations. The pattern of coefficients that emerged from post hoc effect decomposition analyses met the criteria for suppression effects outlined by MacKinnon, Krull, and Lockwood

(2000). Although the direct effect of being schooled abroad on English reading intercept was negative and significant, its indirect effect (through L1 proficiency) was positive and significant ( $p < .01$ ). Removal of this indirect path by fixing it to zero reduced the negative direct effect of number of grades completed abroad on English reading intercept from  $\gamma = -.201, p < .05$ , to  $\gamma = -.106, ns$ . Thus, when the variance in initial English reading scores due to L1 proficiency was controlled, the predictive power of grades completed outside the United States was sharpened. These findings indicate that being schooled outside the United States is related to lower initial levels of English reading only to the extent that it does not contribute to the development of L1 proficiency. Stated differently, the development of L1 proficiency, as a result of being schooled abroad, appears to protect students from the negative effect that having attended school outside the United States would otherwise have on their L2 reading scores.

The hypothesis that L1 proficiency predicts academic achievement through the mediation of English reading growth is consistent with bilingual education theory (e.g., Thomas & Collier, 2002) and with research on cross-language transfer. This hypothesis was also supported in the present study. In post hoc analyses of the Hispanic data, the possibility that L1 proficiency might directly predict academic performance without necessarily requiring the mediation of English literacy development was tested by adding a path from L1 proficiency to academic achievement and by fixing to zero, one at a time, the paths from the two growth factors to the achievement variable. When the path from English intercept to high school achievement was removed, L1 proficiency significantly predicted high school achievement ( $\beta = .266, p < .01$ ). Adding the English reading intercept  $\rightarrow$  high school achievement path back into the model, however, considerably attenuated the predictive strength of L1 proficiency ( $\beta = .104, ns$ ). A similar test with the English reading slope reduced the L1 proficiency  $\rightarrow$  high school achievement regression coefficient from  $\beta = .260, p < .01$ , to  $\beta = .125, ns$ . These findings suggest that L1 proficiency predicts academic performance through the mediation of English literacy development.

The self-report nature of the language proficiency measures used in this research might raise questions about the validity of its findings. The results of longitudinal CFA modeling of MTMM data, however, are comforting regarding the convergent validity, discriminant validity, and temporal stability of the L2 (and, by extension, the L1) proficiency self-ratings used in this study. Partitioning of total variance into its components indicated low proportions of method variance for the L2 proficiency measure. This makes it unlikely that students' self-ratings were substantially contaminated by the biasing effects of response style. Furthermore, if response style selectively distorted the ratings of some students (e.g., overreporting by high self-esteem responders), their estimates of L1 and L2 ability would be biased in the same direction and the correlation between L1 and L2 proficiency ratings would then be inflated. Yet, those measures were found to be uncorrelated in the present research.

In addition, the satisfactory discriminant validity of L2 proficiency self-ratings, established by the MTMM analyses, rules out the rival hypothesis that the pattern of results reported here might be explainable simply in terms of individual differences in a latent general intellectual ability factor. Other sources of evidence in the data point to the same conclusion. For example, students with

higher levels of general cognitive skills would be expected to report higher levels of proficiency in both their native language and in English; yet self-ratings of those two abilities were uncorrelated. Moreover, the path from L2 proficiency to reading growth was not significant in any of the subgroups or in the full sample, and the path from L1 proficiency to reading growth was significant in the full sample and in the Hispanic subsample. These findings are at odds with the hypothesis of a generalized intelligence effect.

### *Multigroup Noninvariance*

The results of the present study suggest that the same educational model might not be applicable to all groups of LEP students. In particular, there is evidence that at least some of the measures included in the model reflect different conceptualizations of the underlying constructs by Hispanic and Asian participants. The generally poor fit of the structural model in the Asian sample and the inability of L1 proficiency to predict growth in English reading in this group suggest that the fundamental assumptions of bilingual education theory might not hold for Asian LEP students. It is possible, however, that L1 proficiency plays an important role also in the English reading growth and general academic development of Asian LEP students, but such influence could not manifest itself because the observed variables included in the model did not adequately represent those students' conceptions of language proficiency. This possibility cannot be ruled out without first testing the same theoretical model with measuring instruments that better reflect the content domain of the constructs as they are conceptualized by Asian students. Thus, the failure to demonstrate configural cultural invariance of a measurement model holds heuristic interest in its own right insofar as it might stimulate investigations of cross-cultural differences in construct conceptualization (e.g., Cheung, Murrmann, Murrmann, & Becker, 2004; Vandenberg, 2002).

In the present study, group differences in the way the constructs were conceptualized might have been intensified by the fact that the two samples included in the multigroup analyses differed greatly in terms of within-group cultural and linguistic homogeneity. Of the 200 Asian students who responded to the question, "What was the first language you learned to speak when you were a child?" (NELS variable "bys18"), 31.5% answered "Chinese" (which includes many different spoken dialects), 14% answered "Filipino," 10.5% answered "Korean," and the rest chose "other." On the other hand, 90.7% of the Hispanic group answered "Spanish" in response to the same question. Moreover, when the Hispanic students were asked to identify the ethnic category that best described their background, 70% of them chose "Mexican." In the Asian sample, instead, only 27.7% (the largest group) answered "Chinese," followed by "Southeast Asian" (25.3%) and by eight other ethnicities. The higher the level of ethnic heterogeneity, especially when combined with marked linguistic diversity, the less likely it is that the same conceptual representation of constructs will be shared by the different subgroups.

The finding that in the Asian sample L1 proficiency, at least as conceptualized in this study, was not at all predictive of either starting levels or of rate of improvement in English reading is also consistent with the well-documented difficulty of transferring language skills from a nonalphabetic to an alphabetic language. As noted earlier, the most frequently spoken language in this group

was Chinese, a nonalphabetic language. Bialystok, McBride-Chang, and Luk (2005) found that although phonological awareness transferred from L1 to L2 in Chinese-speaking children who were learning English, such cross-language transfer did not occur for word decoding ability, a language-specific skill whose transfer is impeded by the absence of a common writing system. Similar cross-language transfer difficulties have been documented not only for young children but also for college-age English language learners who speak a nonalphabetic L1 (Akamatsu, 2003; Holm & Dodd, 1996; Wang & Koda, 2005; Wang et al., 2003).

### *Concluding Comments*

National educational surveys offer many advantages to secondary analysts: representative samples, longitudinal data, large sample sizes, carefully implemented complex sample designs, and rich data sets that include thousands of variables. On the negative side, the variables available for analysis may be inadequate to answer specific research questions. An acknowledged weakness of the present study is the unavailability of valid information about the specific type and duration of L1 and L2 support programs received by LEP students, which would have permitted a more direct test of the bilingual education model. Language support variables are available in the NELS data set and were included as covariates in an earlier version of the structural model diagrammed in Figure 5, but it became clear that their lack of validity severely limited their usefulness. For example, at base year, parents were asked, "Is your eighth grader currently enrolled in a . . . [b]ilingual or bicultural education program" (NELS variable "byp49a"). When parents responded "Yes," only 28% of their children agreed. This disconcerting lack of agreement was probably related to the frequently indiscernible nature of the L1 support programs implemented in the schools. As mentioned earlier, Rossell (2003) argued that widespread misunderstanding about bilingual education and its educational alternatives is shared by students, parents, and teachers. The NELS data set certainly provides evidence that supports this conclusion.

On the other hand, the central focus of this study was on the prediction of English reading trajectories and academic outcomes, not on the prediction of L1 proficiency. Thus, despite the inability to model L1 and L2 support measures, it can still be concluded that L1 proficiency, regardless of how it develops in Hispanic LEP students (i.e., as a result of L1 support services, of being schooled abroad, of cross-linguistic transfer effects, or of as yet unidentified factors), forecasts a favorable rate of growth in English reading skills, which is then predictive of successful short-term (i.e., high school academic achievement) and long-term (i.e., postsecondary educational and occupational attainment) outcomes.

As indicated earlier, transcript information and data for all waves were available for only 30% of the LEP students identified with the selection procedures diagrammed in Figure 1. As a result, one might wonder whether the findings of this study can be generalized to the full LEP sample. Although there were no significant differences in L1 proficiency ratings at base year between the LEP students selected for this study and the LEP students excluded because of incomplete data, there were significant differences on some dimensions. In particular, excluded LEP students exhibited significantly higher drop-out rates, lower SES, and lower self-reported English proficiency at base year than those included

in the sample. Excluded LEP students were also proportionately less likely to be Asian (though equally likely to be Hispanic) than were included LEP students. The critical question, however, is whether the latent growth model tested here, as well as its specific components (i.e., growth process, factorial structure, and structural relations among constructs), had a good fit to the initial LEP sample's data. With respect to this issue, the results of secondary analyses are encouraging. From the initial LEP sample, 1,447 students, who had been excluded because transcripts and/or data from all waves were not available, filled out the first questionnaire. The growth, measurement, and full LGM models were estimated in this subsample after the post-high school achievement factor was removed because of excessive missing data. In each case, model fit was found to be as good as or better than the fit of the same models estimated in the sample tested in this study. Once again, separate model estimation analyses for each ethnic group of excluded LEP students yielded evidence of good fit for Hispanic students and poorer fit for Asian students.

At the same time, the ability to apply these findings to the larger population of LEP students in U.S. schools is undermined by the fact that individual LEP students were declared ineligible for the NELS study if, in the opinion of the school staff, their English literacy was not sufficiently developed to enable them to read and understand the data collection instruments (Spencer, Frankel, Ingels, Rasinski, & Tourangeau, 1990). Thus the range of L2 literacy in this sample is narrower than the range found in the general LEP population. This restriction of range necessarily limits the generalizability of the findings, which can be applied only to LEP students whose English language skills are reasonably well developed. It is hoped that the policy changes in the NCES' approach to large-scale assessment instituted after the NELS data were collected and the renewed commitment to increase participation of LEP students in NCES studies (Olson & Goldstein, 1997) will make it possible for future research to determine the extent to which the model tested in this study can be applied to LEP students with lower initial levels of English proficiency.

With these caveats, the findings of the present research suggest that at least in Hispanic LEP students, native language proficiency is an important predictor of English reading trajectories. Through its association with reading growth, L1 proficiency also forecasts both short-term high school achievement and distal educational and occupational attainment. Confidence in these conclusions is strengthened by the stability of the findings. A model in which the possible confounding influence of various family and school characteristics was statistically controlled by including them as additional covariates yielded a very similar pattern of results. The extent to which existing bilingual education programs promote the development of L1 literacy and the effectiveness of these programs for particular language-minority groups need to be established by methodologically sound educational research. The findings reported here, however, point to the value of maintaining and further developing first-language proficiency for Hispanic (predominantly Mexican American) students, which is the necessary theoretical precondition for exploring the practical efficacy of specific educational interventions.

University of California, Riverside

The influence of cognitive growth in working memory (WM) on mathematical problem solution accuracy was examined in elementary school children ( $N = 353$ ) at risk and not at risk for serious math problem solving difficulties. A battery of tests was administered that assessed problem solving, achievement, and cognitive processing (WM, inhibition, naming speed, phonological coding) in children in 1st, 2nd, and 3rd grade across 3 testing waves. The results were that (a) children identified as at risk for serious math problem solving difficulties in Wave 1 showed less growth rate and lower levels of performance on cognitive measures than did children not at risk; (b) fluid intelligence and 2 components of WM (central executive, visual-spatial sketchpad) in Wave 1 (Year 1) predicted Wave 3 word problem solving solution accuracy; and (c) growth in the central executive and phonological storage component of WM was related to growth in solution accuracy. The results support the notion that growth in WM is an important predictor of children's problem solving beyond the contribution of reading, calculation skills, and individual differences in phonological processing, inhibition, and processing speed.

**Keywords:** working memory, math disabilities, problem solving, phonological processing, executive processing

Word problems are an important part of mathematics programs in elementary schools. This is because word problems help students apply formal mathematical knowledge and skills to real world situations. Much of the evidence indicates that word problem performance improves as children gain greater ability in (a) understanding underlying arithmetic operations (e.g., Rasmussen & Bisanz, 2005), (b) distinguishing between types of word problems on a basis of mathematical operations (e.g., Fayol, Abdi, & Gombert, 1987; Rittle-Johnson, Siegler, & Alibali, 2001), and (c) an effective use of strategies (e.g., Geary, Hoard, Byrd-Craven, & Desoto, 2004; Siegler, 1988). Developmental changes in skills in mathematics do not provide a complete account, however, of

age-related changes in word problem solving. There is evidence that suggests the need for more general cognitive processes, that is, processes nonspecific to mathematics. For example, solving a word problem, such as "15 dolls are for sale. 7 dolls have hats. The dolls are large. How many dolls do not have hats?" involves the development of a variety of mental activities (Barrouillet & Lépine, 2005). Children must access prestored information (e.g., 15 dolls), access the appropriate algorithm (15 minus 7), and apply problem solving process to control its execution (e.g., ignore the irrelevant information). Given the multistep nature of word problems, it seems plausible that working memory (WM) plays a major role in solution accuracy. WM is defined as a processing resource of limited capacity, involved in the preservation of information while simultaneously processing the same or other information (Baddeley & Logie, 1999; Engle, Tuholski, Laughlin, & Conway 1999; Miyake, 2001).

Although there are several models of WM, Baddeley's multi-component model has often been used to explore the role of WM on mathematical problem solving (e.g., Swanson & Beebe-Frankenberg, 2004). Baddeley and Logie (1999) described WM as a limited capacity central executive system that interacts with a set of two passive store systems used for temporary storage of different classes of information: the speech-based phonological loop and the visual-spatial sketchpad. The phonological loop is responsible for the temporary storage of verbal information; items are held within a phonological store of limited duration, and the items are maintained within the store via the process of articulation (inner vocalization). The visual-spatial sketchpad is responsible for the storage of visual-spatial information over brief periods and

---

plays a key role in the generation and manipulation of mental images. Both storage systems are in direct contact with the central executive system. The central executive system is considered to be primarily responsible for coordinating activity within the cognitive system but also devotes some of its resources to increase the amount of information that can be held in the two subsystems (Baddeley & Logie, 1999). A recent formulation of the model (Baddeley, 2000) also includes a temporary multimodal storage component called the *episodic buffer*.

Although WM is a fundamental component in many current theories of children's problem solving (in addition to learning, comprehension, and reasoning), no longitudinal studies (to our knowledge) have explicitly isolated those components of WM most directly related to growth in problem solving, especially in children at risk for word problem solving difficulties. Because WM is made up of three components (central executive, phonological loop, and visual-spatial sketchpad), the question arises as to whether WM as a whole operates on problem solving or whether a certain component is more important. Thus, although there is a strong interrelationship among these components, we sought in the present study to determine whether growth in certain components of WM is related to growth in word problem solving. In this study, we attempted to break out the contributions of WM by focusing on short-term memory (STM) measures, verbal WM measures, and visual-spatial WM measures. In elaborating on the distinction between STM and WM, Cowan (1995) emphasized the role of attentional processes. WM is depicted as a subset of items of information stored in STM that are in turn submitted to limited attentional control processing (see also Engle et al., 1999). This assumes that when the contents of STM are separated from WM what is left of WM is controlled attention or processing related to the central executive system (also referred to in this article as *executive processing* or *the central executive component of WM*). Consequently, to understand the impact of WM to problem solving in terms of executive processing the influence of STM must be partialled out.

### Models of WM and Word Problem Solving

How might growth in WM mediate age-related and individual differences in word problem solving? We consider three models as an explanation of the role of WM in individual and age-related problem solving performance in children: one focuses on the child's knowledge base for arithmetical calculations and components of word problems; another focuses on the storage components of WM, primarily the phonological loop; and the third focuses on the central executive system. The models are not necessarily exclusive of one another (each process can contribute important variance to problem solving to some degree) but suggest that some processes are more important than others.

#### *Knowledge Base*

The first model considers whether age-related differences in the child's knowledge base play a major role in mediating the influence of WM on problem solving. Several capacity models suggest that WM represents an activated portion of declarative long-term memory (LTM) (J. R. Anderson, Reder, & Lebiere, 1996; Cantor & Engle, 1993). That is, WM capacity influences the amount of

resources available to activate knowledge (see Conway & Engle, 1994, for a review of this model). Baddeley and Logie (1999) stated that a major role of WM "is retrieval of stored long-term knowledge relevant to the tasks at hand, the manipulation and recombination of material allowing the interpretation of novel stimuli, and the discovery of novel information or the solution to problems" (p. 31). They further stated that "any increase in total storage capacity beyond that of a given slave system is achieved by accessing either long-term memory (LTM) or other subsystems" (p. 37). Thus, the influence of WM performance on problem solving is related to one's ability to accurately access information (e.g., appropriate algorithm) from LTM to solve the problem. More specifically, a word problem introduces information into WM. The contents of WM are then compared with possible action sequences (e.g., associative links) in LTM (Ericsson & Kintsch, 1995). When a match is found (recognized), the contents of WM are updated and used to generate a solution. This assumption is consistent with current models of problem solving that are based on "recognize-act" models of a cognitive processor (J. R. Anderson et al., 1996; Ericsson & Kintsch, 1995).

In the present study, we assessed whether the retrievability of contents in LTM such as math skills, as well as domain-specific knowledge of the propositions found in word problems, mediates WM and problem solving. These LTM propositions are related to accessing numerical, relational, question, and extraneous information, as well as accessing the appropriate operations and solution algorithms (Hegarty, Mayer, & Monk, 1995; Mayer & Hegarty, 1996; Swanson, Cooney, & Brock, 1993). In the present study, we assumed that the contribution of LTM could be tested by partialing its influence from the correlations between WM and problem solving. Clearly, we only sampled some aspects of LTM, but we assumed that the influence of WM on problem solution accuracy should be eliminated when measures related to LTM (e.g., knowledge of the propositions found in word problems) are partialled from the analysis.

#### *Phonological System*

The second model assumes that the individual and age-related influence of WM on children's mathematic problem solving is primarily moderated by STM storage, the phonological system in particular. Because mathematical word problems are presented in a text format and the decoding and comprehension of text draws on the phonological system (see Baddeley, Gathercole, & Papagno, 1998, for a review), individual differences and age-related differences on problem solving tasks can be attributed to the phonological loop. Several studies assume that STM measures capture a subset of WM performance, the utilization and/or operation of the phonological loop (for a comprehensive review, see Dempster, 1985; Gathercole, 1998). This is because successful performance on STM measures draws on two major components of the phonological loop: a speech-based phonological input store and a rehearsal process (see Baddeley, 1986, for review). Research to date on STM indicates that young children rehearse less and perform more poorly on tasks requiring the short-term retention of order information when compared with older children (Ornstein, Naus, & Liberty, 1975), and children with math disabilities rehearse less when compared with children without math disabilities (e.g., see Geary, 2003, for a review). This suggests inefficient utilization of

the phonological rehearsal process (Henry & Millar, 1993). Because younger children and children with math disabilities have smaller digit spans than older children and children without math disabilities, it is possible they have basic inefficiencies in the storage of phonological input that influence higher level processing, such as comprehending and solving word problems. Developmental and individual differences in the phonological loop, therefore, might be expected to influence some aspects of problem solving, such as computing solutions to problems (Furst & Hitch, 2000). The phonological loop may be able to retain information of verbal form during ongoing calculations. Although not in the domain of math, *per se*, some studies suggest that simple short-term storage has a significant role in accounting for the relationship between WM and several cognitive abilities (Ackerman, Beier, & Boyle, 2005; Colom, Abad, Rebollo, & Shih, 2005; Colom, Flores-Mendoza, Quiroga, & Privado, 2005).

Thus, a simple version of this hypothesis states that individuals at risk for math disabilities and younger children are slower and/or less accurate at processing verbal information (numbers, letters) than average achieving children or older children, and this reduced processing on the participants' part underlies their poor WM and problem solving performance. These assumptions are consistent with a number of bottom-up models of higher order processing, such as comprehension, which view the primary task of executive processing as one of relaying the results of lower level linguistic analyses upward through the language system (Shankweiler & Crain, 1986). Phonologically analyzed information is transferred to WM storage, which in turn is then transferred (thus freeing storage for the next chunk of phonological information) upward through the processing system to promote online extraction of meaning. One of the possible reasons WM span increases as a function of age is because older children and children without math disabilities can name items more rapidly at recall than younger children or children with math disabilities. That is, increases in naming from early to the late childhood years are assumed to enhance the effectiveness of subvocal rehearsal processes and hence reduce the decay of memory items in the phonological store prior to output (Henry & Millar, 1993).

There are clear expectations in the aforementioned model: Individual and age-related changes in children's problem solving are related to the phonological loop. Mathematical proficiency follows automatically from improvements in phonological processing (i.e., because of improved storage and speed of processing information). Therefore, correlations between WM and problem solving should be significantly weakened if measures reflective of the phonological loop are partialled from the analysis. In other words, if age-related differences in problem solving performance and WM are moderated by the phonological system, then the relationship between problem solving and WM should be diminished when measures of the phonological system (e.g., phonological knowledge, speed, STM) are partialled from the analysis.

### *Central Executive System*

The third model incorporates some of the assumptions of the first two models by viewing executive processing as: (a) providing resources to lower order (phonological system) skills and (b) accessing information from LTM. However, the model also views executive processes that are independent of those skills as playing

a major role in individual differences in mathematical problem solving. That is, although individual and age-related differences in problem solving accuracy are possibly related to the retrievability of contents in LTM (e.g., knowledge of specific mathematical relations, general problem solving strategies) and the phonological loop, other activities of the executive system may also underlie the influence of WM on solution accuracy (e.g., Swanson & Ashbaker, 2000; Swanson & Sachse-Lee, 2001). For example, several other cognitive activities (e.g., see Miyake, Friedman, Emerson, Witzki, & Howerter, 2000, for a review), such as controlling subsidiary memory systems, control of encoding and retrieval strategies, attention switching during manipulation of material held in the verbal and visual-spatial systems, and suppressing irrelevant information, have been assigned to the central executive system (Baddeley, 1996; Miyake et al., 2000; Oberauer, Suss, Wilhelm, & Wittman, 2003). Thus, the third model suggests that the central executive system contributes significant variance to individual and age-related differences in problem solving. Thus, in contrast to the aforementioned models that suggest increases in knowledge base and phonological processes play the dominant role in the mediating effects of WM on children's word problem solving, the present model assumes that executive processes also play a major role in mediating problem solving performance. There are clear expectations for this model. The influence of WM on measures of problem solving follows automatically with improvements in performance related to the executive component of WM.

### *Previous Individual and Cross-Sectional Studies*

Some preliminary work has been done in addressing these three models. Studies by Swanson and colleagues (Swanson, 2004; Swanson & Beebe-Frankenberger, 2004; Swanson & Sachse-Lee, 2001) have shown that children with mathematical problem solving difficulties across different age groups perform poorly relative to controls on measures of WM. For example, Swanson and Sachse-Lee (2001) found with children ages 11 to 15 with and without math disabilities that phonological processing, verbal WM, and visual WM contributed unique variance to solution accuracy in word problems. This finding is in line with the current literature suggesting that the development of the phonological system plays an important part in accounting for individual differences in text processing. However, their results also showed that verbal WM processes played just as important a role as phonological processes (i.e., verbal WM reduced the contribution of the ability group contrast variable by approximately 63%) in accounting for the ability group differences in solution accuracy. Thus, there was weak support for the assumption that only the development of bottom-up processes (i.e., the phonological system) mediated deficits in WM processing and its influence on solution accuracy. In a follow-up analysis of Swanson and Beebe-Frankenberger's (2004) study, Swanson (2006) found that when residual variance related to STM was partialled out in the analysis, the component that best predicted problem solving was the central executive system of WM.
